

Air Quality Modeling Technical Support Document 2015 Ozone NAAQS SIP Disapproval Final Action

Office of Air Quality Planning and Standards United States Environmental Protection Agency

1. Introduction

In this technical support document (TSD) we describe the air quality modeling performed to support the EPA's State Implementation Plan Addressing Regional Ozone Transport for the 2015 Ozone National Ambient Air Quality Standards final action. For this final action, air quality modeling is used to project ozone design values¹ at individual monitoring sites to the 2023 analytic year² and to estimate state-by-state contributions to ozone design values at individual monitoring sites in this future year. The projected ozone design values are evaluated to identify ozone monitoring sites that are expected to have nonattainment or maintenance problems for the 2015 ozone National Ambient Air Quality Standards (NAAQS) in the future (i.e., nonattainment and maintenance receptors).³ Ozone contribution data for 2023 is used to quantify projected interstate contributions from emissions in each upwind state to ozone design values at projected nonattainment and maintenance receptors in other states (i.e., in downwind states). The contributions from individual states to nonattainment and maintenance receptors in other states (i.e., upwind states and downwind states, respectively) are evaluated to identify upwind states that contribute greater than or equal to 1 percent of the 2015 ozone NAAQS (i.e., 1 percent of 70 ppb which is 0.70 ppb) to one or more downwind receptors. Upwind states that contribute at or above this threshold to particular receptors are referred to as being "linked" to these receptors. In this action the EPA is disapproving the good neighbor SIPs submitted by Alabama, Arkansas, California, Illinois, Indiana, Kentucky, Louisiana, Maryland, Michigan, Mississippi, Missouri, Nevada, New Jersey, New York, Ohio, Oklahoma, Texas, Utah, and West Virginia, and partially approving/disapproving the good neighbor SIPs submitted by Minnesota and Wisconsin. As described below, in this TSD we present the contribution data for each of these states as well as the other states included in our national scale modeling.

As described in this TSD, the EPA performed air quality modeling for the 2016 base year and 2023 future year to project 2016-centered base period design values to this future year. Ozone source apportionment modeling was performed using emissions projected to 2023 to determine the contributions of total anthropogenic emissions from each state to projected ozone design values at individual monitoring sites nationwide. The modeling for 2023 was used to identify receptors and

¹ The ozone design value for a monitoring site is the 3-year average of the annual fourth-highest daily maximum 8-hour average ozone concentrations at the site.

² The rationale for using 2023as the applicable future analytic year for this transport assessment is described in the preamble for this final action.

³ As described in section 3, the EPA also identified an additional type of maintenance-only receptors based on recent measured data that exceed the NAAQS.

upwind/downwind linkages to inform Step 1 and Step 2 of the 4-step interstate transport framework, respectively.⁴

The remaining sections of this TSD are as follows. Section 2 describes the air quality modeling platform and the evaluation of model predictions of maximum daily averge 8-hour (MDA8) ozone concentrations using measured (i.e., observed) data. Section 3 describes the procedures for projecting ozone design value concentrations and the approach for identifying monitoring sites projected to have nonattainment and/or maintenance problems in 2023. Section 4 describes (1) the source apportionment modeling, (2) the procedures for quantifying contributions to individual monitoring sites including nonattainment and/or maintenance sites, and (3) the evaluation of upwind state contributions to individual receptors in downwind states. Section 5 describes a back-trajectory analysis for each monitor plus modeled receptor in 2023. Appendix A describes the results of a sensitivity analysis designed to investigate the possible causes of ozone under prediction in the 2016v2 modeling for the purpose of improving model performance in the 2016v3 modeling. Appendix B provides model performance statistics and graphics for maximum daily averge 8-hour (MDA8) ozone concentrations in the 2016v3 base year modeling. Appendix C includes tables containing the ozone contributions to each receptor from each state and other individual source "tags" tracked in the source apportionment modeling for 2023. Appendix D contains tables which provide the total upwind state contribution as a percent of the 2023 ozone concentration at each monitor plus modeled receptor. Appendix E contains tables which identify which upwind states are linked to individual downwind receptors.

The input and output modeling files for the 2016 and 2023 modeling to support this final action are available on data drives in the EPA docket office.⁵ A copy of the air quality model input and/or output data can also be obtained by contacting Norm Possiel at <u>possiel.norm@epa.gov</u>.

⁴ See the preamble for a detailed description of the 4-step interstate transport framework. In summary, for Step 1: identify monitoring sites that are projected to have problems attaining and/or maintaining the NAAQS (i.e., nonattainment and/or maintenance receptors); Step 2: identify states that impact those air quality problems in other (i.e., downwind) states sufficiently such that the states are considered "linked" and therefore warrant further review and analysis; Step 3: identify the emissions reductions necessary (if any), applying a multifactor analysis, to eliminate each linked upwind state's significant contribution to nonattainment or interference with maintenance of the NAAQS at the locations identified in Step 1; and Step 4: adopt permanent and enforceable measures needed to achieve those emissions reductions. ⁵ A list of available model input and output data is provided in the file "Air Quality Modeling Files_2016v3 Platform" which can be found in the docket for this final action.

2. Air Quality Modeling Platform

The EPA used version 3 of the 2016-based air quality modeling platform (i.e., 2016v3) to provide the foundational model-input data sets for 2016 and 2023. In addition to emissions data for 2016 and 2023, this platform includes meteorology, initial and boundary condition concentrations, and other inputs representative of the 2016 base year. In response to public comments on the 2016v2 base year and projected emissions inventories, the 2016v3 emissions platform includes numerous updates to both anthropogenic and biogenic emissions and the addition of NOx emissions from lightning strikes. These updates are described in the document *Preparation of Emissions Inventories for the 2016v3 North American Emissions Modeling Platform* available in the docket for this final action.

2.1 Air Quality Model Configuration and Model Simulations

The photochemical model simulations performed for this final action used the Comprehensive Air Quality Model with Extensions (CAMx version 7.10, Ramboll, 2021). CAMx is a threedimensional grid-based Eulerian air quality model designed to simulate the formation and fate of oxidant precursors, primary and secondary particulate matter concentrations, and deposition over regional and urban spatial scales (e.g., the contiguous U.S.). Consideration of the different processes (e.g., transport and deposition) that affect primary (directly emitted) and secondary (formed by atmospheric processes) pollutants at the regional scale in different locations is fundamental to understanding and assessing the effects of emissions on air quality concentrations. For this final action, as in the CSAPR Update, Revised CSAPR Update, and the proposed disapprovals, the EPA used the CAMx Ozone Source Apportionment Technology/Anthropogenic Precursor Culpability Analysis (OSAT/APCA) technique⁶ to model ozone contributions, as described below in section 4.

The geographic extent of the modeling domains that were used for air quality modeling in this analysis are shown in Figure 2-1. The large outer domain covers the 48 contiguous states along with most of Canada and all of Mexico with a horizontal resolution of 36 x 36 km (i.e., 36 km domain). The inner domain covers the 48 contiguous states along with adjacent portions of Canada and Mexico at 12 x 12 km resolution (i.e., 12 km domain).

 $^{^{6}}$ As part of this technique, ozone formed from reactions between biogenic VOC and NO_X with anthropogenic NO_X and VOC are assigned to the source of anthropogenic emissions.

Figure 2-1. Air quality modeling domains.

CAMx requires a variety of input files that contain information pertaining to the modeling domain and simulation period. These include gridded, hourly emissions estimates and meteorological data, and initial and boundary concentrations. Separate emissions inventories were prepared for the 2016 base year and the 2023 projection. All other inputs (i.e., meteorological fields, initial concentrations, ozone column, photolysis rates, and boundary concentrations) were specified for the 2016 base year model application and remained unchanged for the projection-year model simulation.⁷

The 12 km CAMx model simulations performed for this final action are listed in Table 2-1. The simulation period for each run was preceded by a 15-day ramp-up period.

Analytic Year	Model Run	Case Name	Simulation Period
2016	2016 baseline	2016gf	Annual
2022	2023 baseline	2023gf	Annual
2023	2023 state total anthropogenic contributions	2023gf_ussa	May - September

Table 2-1. Model run name, case name and simulation period for each model run.⁸

⁷ The EPA used the CAMx7.1chemparam.CB6r5_CF2E chemical parameter file for all the CAMx model runs described in this TSD.

⁸ Because the model simulations run in Greenwich Mean Time (GMT), the actual simulation period included October 1 in order to obtain MDA8 ozone concentrations based on local time for September 30.

2.2 Meteorological Data for 2016

This section describes the meteorological modeling that was performed to provide meteorological data for 2016 for input to air quality modeling. Note that the EPA used the same meteorological data for the 2016v3 air quality modeling as was used for the 2016v2 air quality modeling.

The 2016 meteorological data were derived from running Version 3.8 of the Weather Research Forecasting Model (WRF) (Skamarock, et al., 2008). The meteorological outputs from WRF include hourly-varying horizontal wind components (i.e., speed and direction), temperature, moisture, vertical diffusion rates, and rainfall rates for each grid cell in each vertical layer. Selected physics options used in the WRF simulations include Pleim-Xiu land surface model (Xiu and Pleim, 2001; Pleim and Xiu, 2003), Asymmetric Convective Model version 2 planetary boundary layer scheme (Pleim 2007a,b), Kain-Fritsch cumulus parameterization (Kain, 2004) utilizing the moistureadvection trigger (Ma and Tan, 2009), Morrison double moment microphysics (Morrison et al., 2005; Morrison and Gettelman, 2008), and RRTMG longwave and shortwave radiation schemes (Iacono et.al., 2008).

Both the 36 km and 12 km WRF model simulations utilize a Lambert conformal projection centered at (-97,40) with true latitudes of 33 and 45 degrees north. The 36 km domain contains 184 cells in the X direction and 160 cells in the Y direction. The 12 km domain contains 412 cells in the X direction and 372 cells in the Y direction. The atmosphere is resolved with 35 vertical layers up to 50 mb (see Table 2-2), with the thinnest layers being nearest the surface to better resolve the planetary boundary layer (PBL).

The 36 km WRF model simulation was initialized using the 0.25-degree GFS analysis and 3hour forecast from the 00 GMT, 06 GMT, 12 GMT, and 18 GMT simulations. The 12 km model was initialized using the 12 km North American Model (12NAM) analysis product provided by National Climatic Data Center (NCDC).⁹ The 40 km Eta Data Assimilation System (EDAS) analysis (ds609.2) from the National Center for Atmospheric Research (NCAR) was used where 12NAM data was unavailable.¹⁰ Analysis nudging for temperature, wind, and moisture was applied above the boundary layer only. The model simulations were conducted continuously. The 'ipxwrf' program was used to initialize deep soil moisture at the start of the run using a 10-day spin-up period (Gilliam and Pleim, 2010). Land use and land cover data were based on the USGS for the 36NOAM simulation and the

¹⁰ https://www.ready.noaa.gov/edas40.php.

2011 National Land Cover Database (NLCD 2011) for the 12US simulation. Sea surface temperatures were ingested from the Group for High Resolution Sea Surface Temperatures (GHRSST) (Stammer et al., 2003) 1 km SST data. Additionally, lightning data assimilation was utilized to suppress (force) deep convection where lightning is absent (present) in observational data. This method is described by Heath et al. (2016) and was employed to help improve precipitation estimates generated by the model.

WRF Layer	Height (m)	Pressure (mb)	Sigma
35	17,556	5000	0.000

Table 2-2. Vertical layers and their approximate height above ground level.

Details of the annual 2016 meteorological model simulation and evaluation are provided in a separate technical support document, which can be found in the docket for this final action.¹¹

The meteorological data generated by the WRF simulations were processed using wrfcamx v4.7 (Ramboll 2021) meteorological data processing program to create 35-layer gridded model-ready meteorological inputs to CAMx. In running wrfcamx, vertical eddy diffusivities (Kv) were calculated using the Yonsei University (YSU) (Hong and Dudhia, 2006) mixing scheme. We used a minimum Kv of 0.1 m²/sec except for urban grid cells where the minimum Kv was reset to 1.0 m²/sec within the lowest 200 m of the surface in order to enhance mixing associated with the nighttime "urban heat island" effect. In addition, we invoked the subgrid convection and subgrid stratoform cloud options in our wrfcamx run for 2016.

2.3 Initial and Boundary Concentrations

The lateral boundary and initial species concentrations for the 36 km simulations were derived from outputs of a three-dimensional global atmospheric chemistry model, GEOS-Chem global model (I. Bey, et al., 2001) which was run for 2016. The GEOS-Chem predictions were used to provide one-way dynamic boundary concentrations at one-hour intervals and an initial concentration field for the 36 km CAMx simulations for 2016 and 2023. In the 2016v2 modeling for the proposed actions, the EPA used the hemispheric version of the Community Multi-scale Air Quality Model (H-CMAQ).¹² The basis for selecting GEOS-Chem for the 2016v3 modeling is discussed in Appendix A.

Air quality modeling for the 36 km domain was used to provide initial and boundary conditions for the nested 12 km domain model simulations. Both the 36 km and 12 km modeling domains have 35 vertical layers with a top at about 17,550 meters, or 50 millibars (mb). The model simulations produce hourly air quality concentrations for each grid cell across each modeling domain. Modeling for the 36 km domain was performed for 2016 and 2023. Outputs from the 2016 36 km simulation were used to provide initial and boundary conditions for the 2016 12 km model simulation. Outputs from the 2023 36 km simulation were used to provide initial and boundary conditions for the 2016 12 km model simulations for the 202312 km simulations.

¹¹ Meteorological Modeling for 2016.docx.

¹² More information about the H-CMAQ model and other applications using this tool is available at: <u>https://www.epa.gov/cmaq/hemispheric-scale-applications</u>. Note that the EPA used the same initial and boundary conditions for the 2016v2 air quality modeling as was used for the 2016v1 air quality modeling.

2.5 Air Quality Model Evaluation

An operational model performance evaluation for ozone was conducted to examine the ability of the 2016v3 CAMx modeling system to simulate 2016 measured MDA8 ozone concentrations. This evaluation focused on graphical analyses and statistical metrics of model predictions versus observations. Details on the evaluation methodology, the calculation of performance statistics, and results are provided in Appendix B. Overall, the ozone model performance statistics for the CAMx 2016v3 simulation are within the ranges found in other recent peer-reviewed applications (e.g., Simon et al, 2012 and Emory et al, 2017). As described in Appendix B, model performance for the 2016v3 platform is notably improved compared to model performance for the 2016v2 platform. The model performance results demonstrate the scientific credibility of our 2016v3 modeling platform. These results provide confidence in the ability of the modeling platform to provide a reasonable projection of expected future year ozone concentrations and contributions. Model performance statistics for individual monitoring sites for the period May through September are provided in a spreadsheet file in the docket for this final action.¹³

3. Identification of Future Nonattainment and Maintenance Receptors in 2023

3.1 Definition of Nonattainment and Maintenance Receptors

The ozone predictions from the 2016 base year and future case CAMx model simulations were used to calculate average and maximum ozone design values for the 2023 analytic year using the approach described in this section. Following the approach used for the proposed actions, we evaluated projected average and maximum design values in conjunction with the most recent measured ozone design values (i.e., 2021)¹⁴ to identify nonattainment or maintenance sites in each of the three future years. Those monitoring sites with future year average design values that exceed the NAAQS (i.e., average design values of 71 ppb or greater)¹⁵ and that are currently measuring nonattainment are considered to be nonattainment receptors. Similarly, monitoring sites with a projected maximum design value that exceeds the NAAQS are projected to be maintenance receptors. Maintenance-only receptors include those monitoring sites where the projected average design value is below the NAAQS, but the maximum design value is above the NAAQS, and

¹³ CAMx 2016v2 MDA8 O3 Model Performance Stats by Site.

¹⁴ The 2021 design values are the most current official design values available for use in this final action. The 2021 ozone design values, by monitoring site, can be found in the following file in the docket: 2010 thru 2021 Ozone Design Values. ¹⁵ In determining compliance with the NAAQS, ozone design values are truncated to integer values. For example, a design value of 70.9 parts per billion (ppb) is truncated to 70 ppb which is attainment. In this manner, design values at or above 71.0 ppb are considered to be violations of the NAAQS.

monitoring sites with projected average design values that exceed the NAAQS, but for which current design values based on measured data do not exceed the NAAQS.¹⁶ In addition, as described in the preamble for this final action, the EPA received comments stating that our methodology to identify receptors in 2023 appears overly optimistic in light of current measured data. These commenters suggest that the EPA give greater weight to current measured data as part of the method for identifying projected receptors. In response to these comments the EPA has developed an additional maintenance-only receptor category, which includes what we refer to as "violating monitor" receptors. Specifically, the EPA has identified "violating monitor" receptors as those monitoring sites with measured 2021 and preliminary 2022 design values *and* 4th high maximum daily MDA8 ozone concentrations in both 2021 and 2022 (preliminary data) that exceed the NAAQS, although model-projected design values for 2023 are below the NAAQS.¹⁷

The procedures for calculating projected average and maximum design values are described below. The monitoring sites that are projected to be nonattainment and/or maintenance-only receptors for the ozone NAAQS in the 2023 are used for assessing the contribution of emissions in upwind states to downwind nonattainment and maintenance of the 2015 ozone NAAQS as part of this final action.

3.2 Approach for Projecting Ozone Design Values

The ozone predictions from the 2016 and 2023 model simulations were used to project ambient (i.e., measured) ozone design values (DVs) to 2023 based on an approach that follows from the EPA's guidance for attainment demonstration modeling (US EPA, 2018),¹⁸ as summarized here. The modeling guidance recommends using 5-year weighted average ambient design values centered on the base modeling year as the starting point for projecting average design values to the future. Because 2016 is the base emissions year, we used the average ambient 8-hour ozone design values for the period 2014 through 2018 (i.e., the average of design values for 2014-2016, 2015-2017 and 2016-2018) to calculate the 5-year weighted average design values (i.e., 2016-centered design values). The

¹⁶ The EPA's modeling guidance notes that projecting the highest (i.e., maximum) design value from the base period provides an approach for evaluating attainment in periods with meteorological conditions especially conducive to high ozone concentrations.

¹⁷ 2021 4th high MDA8 ozone concentrations and preliminary 2022 design values and 4th high MDA8 ozone concentrations for violating monitor receptors are provided in Table 3-3. Daily MDA8 ozone concentrations which can be used to identify the 4th values in 2021 and the preliminary 4th high values in 2022 for other monitoring sites can be obtained from data files available for download at the following website <u>https://www.epa.gov/outdoor-air-quality-data/download-daily-data</u>

¹⁸ The EPA's ozone attainment demonstration modeling guidance is referred to as "the modeling guidance" in the remainder of this document.

5-year weighted average ambient design value at each site was projected to 2023 using the Software for Model Attainment Test Software – Community Edition (SMAT-CE)¹⁹. This program calculates the 5-year weighted average design value based on observed data and projects future year values using the relative response predicted by the model. Equation (3-1) describes the recommended model attainment test in its simplest form, as applied for monitoring site *i*:

$$(DVF)_i = (RRF)_i * (DVB)_i$$
 Equation 3-1

DVF_i is the estimated design value for the future year at monitoring site *i*; *RRF*_i is the relative response factor for monitoring site *i*; and *DVB*_i is the base period design value monitored at site *i*. The relative response factor for each monitoring site (*RRF*)_i is the fractional change in MDA8 ozone between the base and future year. The RRF is based on the average ozone on model-predicted "high" ozone days in grid cells in the vicinity of the monitoring site. The modeling guidance recommends calculating RRFs based on the highest 10 modeled ozone days in the base year simulation at each monitoring site. Specifically, the RRF for an individual monitoring site is the ratio of the average MDA8 ozone concentration in the future year to the average MDA8 concentration in the 2016 base year. The average values are calculated using MDA8 model predictions in the future year and in 2016 for the 10 highest days in the 2016 base year modeling. For cases in which the base year model simulation does not have 10 days with ozone values >= 60 ppb at a site, we use all days with ozone >= 60 ppb, as long as there were at least 5 days that meet this criterion. At monitor locations with less than 5 days with modeled 2016 base year ozone >= 60 ppb, no RRF or DVF is calculated for the site and the monitor in question was not included in this analysis.

The modeling guidance recommends calculating the RRF using the base year and future year model predictions from the cells immediately surrounding the monitoring site along with the grid cell in which the monitor is located. In this approach the RRF was based on a 3 x 3 array of 12 km grid cells centered on the location of the grid cell containing the monitor.

As in the proposal, the EPA also projects design values based on a modified version of the "3 x 3" approach for those monitoring sites located in coastal areas. In this alternative approach, the EPA eliminated from the RRF calculations the modeling data in those grid cells that are dominated by water (i.e., more than 50 percent of the area in the grid cell is water) and that do not contain a monitoring site (i.e., if a grid cell is more than 50 percent water but contains an air quality monitor, that cell would remain in the calculation). The choice of more than 50 percent of the grid cell area as

¹⁹ Software download and documentation available at <u>https://www.epa.gov/scram/photochemical-modeling-tools</u>

water as the criteria for identifying overwater grid cells is based on the treatment of land use in the Weather Research and Forecasting model (WRF).²⁰ Specifically, in the WRF meteorological model those grid cells that are greater than 50 percent overwater are treated as being 100 percent overwater. In such cases the meteorological conditions in the entire grid cell reflect the vertical mixing and winds over water, even if part of the grid cell also happens to be over land with land-based emissions, as can often be the case for coastal areas. Overlaying land-based emissions with overwater meteorology may be representative of conditions at coastal monitors during times of on-shore flow associated with synoptic conditions and/or sea-breeze or lake-breeze wind flows. But there may be other times, particularly with off-shore wind flow when vertical mixing of land-based emissions may be too limited due to the presence of overwater meteorology. Thus, for this modeling projected average and maximum design values were calculated for individual monitoring sites based on both the "3 x 3" approach as well as the alternative approach that eliminates overwater cells in the RRF calculation for near-coastal areas (i.e., "no water" approach).

For both the "3 x 3" approach and the "no water" approach, the grid cell with the highest base year MDA8 ozone concentration on each day in the applicable array of grid cells surrounding the location of the monitoring site²¹ is used for both the base and future components of the RRF calculation. That is, the base and future year data are paired in space for the grid cell that has the highest MDA8 concentration on the given day.

The approach for calculating projected maximum design values is similar to the approach for calculating the projected average design values. To calculate projected maximum design values we start with the highest (i.e., maximum) ambient design value from the 2016-centered 5-year period (i.e., the maximum of design values from 2014-2016, 2014-2017, and 2016-2018). The base period maximum design value at each site was projected to 2023using the site-specific RRFs, as determined using the procedures for calculating RRFs described above.

For this final action, the EPA is relying upon design values based on the "no water" approach for identifying nonattainment and maintenance receptors and for calculating contributions, as described in section 4, below.

²⁰ <u>https://www.mmm.ucar.edu/weather-research-and-forecasting-model.</u>

 $^{^{21}}$ For the "3 x 3" approach the applicable array contains the 9 grid cells that surround and include the grid cell containing the monitoring site. The applicable array for the "no water" approach includes the grid cell containing the monitoring site along with the subset of the "3 x 3" grid cells that are not classified as "water" grid cells using the criteria described in this TSD.

Consistent with the truncation and rounding procedures for the 8-hour ozone NAAQS, the projected design values are truncated to integers in units of ppb.²² Therefore, projected design values that are greater than or equal to 71 ppb are considered to be violating the 2015 ozone NAAQS. For those sites that are projected to be violating the NAAQS based on the projected average design values, we examined the design values for 2021, which are the most recent concurred measured design values at the time of this final action.²³ As noted above, we identify nonattainment receptors as those sites that are violating the NAAQS based on current measured air quality and also have projected average design values of 71 ppb or greater. Maintenance-only receptors identified based on monitoring plus modeling include both (1) those sites with projected average design values above the NAAQS that are currently measuring clean data and (2) those sites with projected average design values below the level of the NAAQS, but with projected maximum design values of 71 ppb or greater.²⁴ As noted above, the EPA also identified as maintenance-only receptors those monitoring sites with measured 2021 and preliminary 2022 design values *and* 4th high maximum daily MDA8 ozone concentrations in both 2021 and 2022 (preliminary data) that exceed the NAAQS, although model-projected design values for 2023 are below the NAAQS.

The 2016-centered base period average and maximum design values, the projected average and maximum design values for 2023 and the 2021 design values for monitoring sites that are projected to be nonattainment or maintenance-only receptors in 2023 based on monitoring and modeling using the "no water" approach are provided in Tables 3-1 and 3-2, respectively.²⁵ In total, in the 2023 base case there are a total of 33 projected modeling-based receptors nationwide including

²² 40 CFR Part 50, Appendix U to Part 50 – Interpretation of the Primary and Secondary National Ambient Air Quality Standards for Ozone.

²³ Official, concurred ozone design values for 2010 through 2021 are provided in the file: 2010 Thru 2021Ozone Design Values. Preliminary, un-concurred, 2022 design values are provided in the file Preliminary_2022 Design Values. Both of these files can be found in the docket for this final action.

 $^{^{24}}$ In addition to the maintenance-only receptors, the projected nonattainment receptors are also maintenance receptors because the maximum design values for each of these sites is always greater than or equal to the average design value. 25 The "3 x 3" approach and the "no water" approach result in the same set of receptors. That is, the receptors identified based on the "3 x 3" approach are also the receptors identified based on the "no water" approach. However, using design values from the "3 x 3" approach, the maintenance-only receptor at site 550590019 in Kenosha County, WI would become a nonattainment receptor because the average design value with the "3 x 3" approach is 72.0 ppb versus 70.8 ppb with the "no water" approach. In addition, the maintenance-only receptor at site 090099002 in New Haven County, CT would become a nonattainment receptor using the "no water" approach because the average design value with the "3 x 3" approach is 71.2 ppb versus 70.5 ppb with the "no water" approach.

Projected design values for 2023 based on both the "3 x 3" and "no water" approaches for individual monitoring sites nationwide are provided in the file "2016v3_DVs_state_contributions" which can be found in the docket for this final action.

14 nonattainment receptors in 9 different counties and 19 maintenance-only receptors in 13 additional counties (Harris County, TX has both nonattainment and maintenance-only receptors).²⁶

The projected average and maximum design values for 2023 and the 2021 and preliminary 2022 design values and the 2021 and preliminary 2022 4th high values for monitoring sites that are identified as "violating monitor" maintenance-only receptors in 2023 are provided in Tables 3-3. There are 49 monitoring sites that are identified as "violating-monitor" maintenance-only receptors in 2023. As noted earlier in this section, the EPA uses the approach of considering "violating-monitor" maintenance-only receptors as confirmatory of the proposal's identification of receptors and does not implicate additional linked states in this final action. Rather, using this approach serves to strengthen the analytical basis for our Step 2 findings by establishing that many upwind states covered in this action are also projected to contribute above 1 percent of the NAAQS to these additional "violating monitor" maintenance-only receptors.

²⁶ The EPA's modeling also projects that three monitoring sites in the Uinta Basin (i.e., monitor 490472003 in Uintah County, Utah and monitors 490130002 and 490137011 in Duchesne County, Utah) will have average design values above the NAAQS in 2023. However, as noted in the proposed rule, the Uinta Basin nonattainment area was designated as nonattainment for the 2015 ozone NAAQS not because of an ongoing problem with summertime ozone (as is usually the case in other parts of the country), but instead because it violates the ozone NAAQS in winter. The main causes of the Uinta Basin's wintertime ozone are sources located at low elevations within the Basin, the Basin's unique topography, and the influence of the wintertime meteorologic inversions that keep ozone and ozone precursors near the Basin floor and restrict air flow in the Basin. Because of the localized nature of the ozone problem at these sites the EPA has not identified these three monitors as receptors in Step 1 of this proposed rule.

*2022 preliminary design values are based on 2022 measured MDA8 concentrations provided by state air agencies to the EPA's Air Quality System (AQS), as of January 3, 2023.

4. Ozone Contribution Modeling

As noted above, the EPA performed nationwide, state-level ozone source apportionment modeling using the CAMx OSAT/APCA technique to provide data on the contribution of projected 2023 NO_X and VOC emissions from anthropogenic source sectors in each state. The state-by-state anthropogenic source apportionment modeling is described in section 4.1. In section 4.2 we describe the method for calculating the average contribution metric for each source apportionment model run and in section 4.3 we present the results of the state-by-state all anthropogenic modeling.

4.1 State-by-State All Anthropogenic Modeling

In the state-by-state source apportionment model run, we tracked the ozone formed from each of the following contribution categories (i.e., "tags"):

- States anthropogenic NO_X and VOC emissions from each of the contiguous 48 states and the District of Columbia tracked individually (emissions from all anthropogenic sectors in a given state were combined);
- Biogenics biogenic NOx and VOC emissions domain-wide;
- Initial and Boundary Concentrations air quality concentrations used to initialize the 12 km model simulation and air quality concentrations transported into the 12 km modeling domain from the lateral boundaries;
- Tribes the collective emissions from those tribal lands for which we have point source inventory data in the 2016v3 emissions platform (we did not model the contributions from individual tribes);
- Canada and Mexico collective anthropogenic emissions from sources in the portions of Canada and Mexico that are within the 12 km modeling domain (contributions from Canada and Mexico were not modeled separately);
- Fires combined emissions from wild and prescribed fires domain-wide within the 12 km

modeling domain;

- Offshore total emissions from offshore marine vessels and offshore drilling platforms; and
- NOx emissions from lightning strikes.

The above-listed tagged sources account for all ozone sources simulated by the model such that the sum of tagged ozone contributions adds to the total modeled ozone at each hour and grid cell. The source apportionment modeling provided hourly contributions to ozone from anthropogenic NO_X and VOC emissions in each state, individually, to ozone concentrations in each model grid cell. The contributions to ozone from chemical reactions between biogenic NO_X and biogenic VOC emissions were modeled and assigned to the "biogenic" category. The contributions from wildfire and prescribed fire NO_X and VOC emissions were modeled and assigned to the "fires" category. The contributions from the "biogenic", "offshore", and "fires" categories are not assigned to individual states nor are they included in the state contributions.

4.2 Method for Calculating the Contribution Metric

As noted above, CAMx state-by-state source apportionment model runs for 2023 were performed to obtain contributions for the period May through September using the projected 2023 emissions and 2016 meteorology. The resulting hourly contributions²⁷ from each tag were processed to calculate an 8-hour average contribution metric value for each tag at each monitoring site. The contribution metric values at each individual monitoring site are calculated using model predictions for the grid cell containing the monitoring site. The process for calculating the average contribution metric uses the source apportionment outputs in a "relative sense" to apportion the projected average design value at each monitoring location into contributions from each individual tag. This process is similar in concept to the approach described above for using model predictions to calculate future year ozone design values.

The basic approach used to calculate the average contribution metric values for 2023 is described by the following steps:

- For the model grid cells containing an ozone monitoring site, calculate the 8-hour average contribution from each source tag to each monitoring site for the time period of the 2023 modeled MDA8 ozone concentration on each day:
- (2) Average the MDA8 concentrations for the top 10 modeled ozone concentration days in 2023 and average the 8-hour contributions for each of these same days for each tag;

 $^{^{27}}$ Contributions from anthropogenic emissions under "NO_X-limited" and "VOC-limited" chemical regimes were combined to obtain the net contribution from NO_X and VOC anthropogenic emissions in each state.

- (3) Divide the 10-day average contribution for each tag by the corresponding 10-day average concentration to obtain a Relative Contribution Factor (RCF) for each tag at each monitor; and
- (4) Multiply the 2023 average design values by the corresponding RCF to produce the average contribution metric value for each tag at each monitoring site in 2023.

These steps are written out mathematically in Equation 4-1 where $C_{t,i}$ represents the contribution metric value from tag, t, to monitor, i, $DVF_{2023,i}$ represents the projected 2023 future year average DV at monitor, i, $O3C_{t,top10,i}$ is the average ozone *contribution* to MDA8 ozone from tag, t, across the top-10 future year MDA8 modeled days at monitor, i, and, $O3_{top10,i}$ is the average ozone *concentration* across the top-10 future year MDA8 modeled days at monitor, i.

$$C_{t,i} = DVF_{2023,i} \times \frac{O3C_{t,top10,i}}{O3_{top10,i}}$$
Equation 4-1

The contribution metric values calculated from step 4 are truncated to two digits to the right of the decimal (e.g., a calculated contribution of 0.78963... is truncated to 0.78 ppb). As a result of truncation, the tabulated contributions may not always sum to the future year average design value at individual monitoring sites. In addition, when calculating the contribution metric values we applied a criteria that 5 or more of the top 10 model-predicted concentration days must have MDA8 concentrations ≥ 60 ppb in the future year in order to calculate a valid contribution metric. The criterion of having at least 5 days with MDA8 ozone concentrations ≥ 60 ppb was chosen to avoid including contributions on days that are well below the NAAQS in the calculation of the contribution metric. Using a minimum of 5 days up to a maximum of 10 days with MDA8 ozone ≥ 60 ppb aligns with recommendations in the EPA's air quality modeling guidance for projecting future year design values, as described above.

The contribution metric values for monitoring sites nationwide for the 2023 state-by-state source apportionment modeling s are provided in the file "2016v3_DVs_state_contributions" which can be found in the docket of this final action. Note that this file contains data for monitoring sites that meet the criteria for calculating valid contribution metric values, as described above.²⁸

²⁸ Contribution metric values were not calculated for the Seattle Washington receptor because there were fewer than 5 days with future year MDA8 ozone concentrations ≥ 60 ppb at this receptor.

4.3 Results of State-by-State All Anthropogenic Modeling

The largest contribution from each state to monitoring plus modeled downwind receptors in 2023 is provided in Table 4-1.²⁹ The largest contribution from each state to "violating monitor" receptors in 2023 is provided in Table 4-2.

The contribution metric values from each state and the other source tags at individual nonattainment and maintenance-only sites in the 2023 state-by-state all anthropogenic model runs are provided in Appendix C. A table with the total upwind state collective contribution expressed as the percent of the 2023 ozone design value is provided in Appendix D. The upwind states linked to each downwind receptor are identified in Appendix E.

Table 4-1. Largest contribution from each state to downwind nonattainment and maintenance-only receptors in 2023 (ppb).

	Largest Contribution	Largest Contribution
	to Downwind	to Downwind
	Nonattainment	Maintenance-Only

In CSAPR, the CSAPR Update, and the Revised CSAPR Update, and in the proposal for this final action the EPA used a contribution screening threshold of 1 percent of the NAAQS to identify upwind states that may significantly contribute to downwind nonattainment and/or maintenance problems and which warrant further analysis to determine if emissions reductions might be required from each state to address the downwind air quality problem. The EPA determined that 1 percent was an appropriate threshold to use in Step 2 because there were important, even if relatively small, contributions to identified nonattainment and maintenance receptors from multiple upwind states. The EPA has historically found that the 1 percent threshold is appropriate for identifying interstate transport linkages for states collectively contributing to downwind ozone nonattainment or maintenance problems because that threshold captures a high percentage of the total pollution transport affecting downwind receptors. The EPA received numerous comments on the use of the 1 percent screening threshold. Responses to these comments can be found in the preamble and Response to Comments (RTC) document for this final action.

Based on the maximum downwind contribution data in Table 4-1, the following 21 states contribute at or above the 0.70 ppb threshold to downwind nonattainment receptors in 2023: Alabama, Arkansas, California, Illinois, Indiana, Kentucky, Louisiana, Maryland, Michigan, Mississippi, Missouri, Nevada, New Jersey, New York, Ohio, Oklahoma, Pennsylvania, Texas, Utah, Virginia, and West Virginia. Based on the maximum downwind contribution data also in Table 4-1, the following 23 states contribute at or above the 0.70 ppb threshold to downwind modeling-based maintenance-only receptors in 2023: Arizona, Arkansas, California, Illinois, Indiana, Iowa, Kentucky, Louisiana, Maryland, Michigan, Minnesota, Mississippi, Missouri, Nevada, New Jersey, New Mexico, New York, Ohio, Oklahoma, Texas, Virginia, West Virginia, and Wisconsin. Finally, based on the maximum downwind contribution in Table 4-2, the following additional states contribute at or above the 0.70 ppb threshold to downwind violating monitor maintenance-only receptors in 2023: Kansas and Tennessee. The EPA notes that Arizona, Iowa, Kansas, New Mexico, Tennessee, and Wyoming fall into one of two categories: (a) not linked to downwind receptors based on the 2016v2 modeling for the proposal, but that are now linked based on the 2016v3 modeling or are linked to a violating monitor; or (b) were linked to any receptors based on the 2016v3 modeling for the proposal, but that are now not linked to any receptors based on the 2016v3 modeling or under the definition of receptors used at proposal.

The contributions for individual upwind/downwind linkages for each upwind state are provided in Appendix D. The upwind states linked to each receptor are provided in Appendix E.

5. Back Trajectory Analysis

As part of the assessment of interstate transport, the EPA used the HYSPLIT model (Stein, et al., 2017) to provide a "transport climatology" for individual nonattainment and maintenance-only receptors in 2023. This "transport climatology" provides a semi-quantitative approach to identify the predominant transport patterns and interannual variability in transport for days with measured exceedances. In this regard, the information from this analysis provides a qualitative method to corroborate upwind-downwind linkages derived from the air quality contribution modeling. In this analysis the EPA ran the HYSPLIT model to construct 96-hour back trajectories for days with measured exceedances during 2010 through 2021 at individual receptors. Back trajectories were created for three start times on each exceedance day (8:00 am, 12:00 pm, and 3:00 pm Local Time for each of six vertical elevations (100 m, 250 m, 500 m, 750 m, 1000 m, and 1500 m. Meteorological data from the North American Mesoscale meteorological model (NAM) with 12 km horizontal resolution were used in the HYSPLIT runs. The HYSPLIT outputs were processed to determine the number of trajectory segments that crossed over a particular area.³⁰ Each HYSPLIT hourly segment

³⁰ The HYSPLIT segments were processed for a 0.25 degree (approximately 27 km) grid cell. Each grid cell constitutes a particular area.

was counted individually based on segment intersections. For visualization, the trajectory segment counts were further processed using a 7-element Hanning Function.

Plots showing the back trajectories from each receptor are provided in the following documents which can be found in the docket of this final action:

"Exceedance Day Trajectory Analysis_2010-2021_Part 1" and "Exceedance Day Trajectory Analysis_2010-2021_Part 2"

Part 1 contains composite multi-start time, multi-elevation plots of exceedance day back trajectories for each year individually for each receptor.

Part 2 contains composite multi-start time, multi-year composite plots of 500 m and 750 m exceedance day back trajectories for each receptor. These two elevations were selected as generally representative of summertime mid-boundary layer transport.

Appendix A

Model Performance Sensitivity Analysis

As noted in the preamble for this final action, in response to comments the EPA examined the temporal and spatial characteristics of model under prediction in the 2016v2 modeling to investigate the possible causes of under prediction of MDA8 ozone concentrations in different regions of the U.S. The EPA's analysis indicates that the under prediction was most extensive during May and June with less bias during July and August in most regions of the U.S. For example, in the Upper Midwest region model under prediction was larger in May and June compared to July through September. Specifically, the normalized mean bias for days with measured concentrations \geq 60 ppb improved from a 21.4 percent under prediction for May and June to a 12.6 percent under prediction in the period July through September. As highest by the presentation materials in this Appendix, the seasonal pattern in bias in the Upper Midwest region improves somewhat gradually with time from the middle of May to the latter part of June. In view of the seasonal pattern in bias in the Upper Midwest and in other regions of the U.S., EPA focused its investigation of model performance on model inputs that, by their nature, have the largest temporal variation within the ozone season. These inputs include emissions from biogenic sources and lightning NOx, and contributions from transport of international anthropogenic emissions and natural sources into the U.S. Both biogenic and lightning NOx emissions in the U.S. dramatically increase from spring to summer.^{1,2} In contrast, ozone transported into the U.S. from international anthropogenic and natural sources peaks during the period March through

attributed to lightning-induced nitrogen oxides during summertime over the Mountain West States. NPJ Clim Atmos Sci. 2020 Jan 30;3:6. doi: 10.1038/s41612-020-0108-2. PMID: 32181370; PMCID: PMC7075249.

June, with lower contributions during July through September.^{3,4} To investigate the impacts of the sources, EPA conducted sensitivity model runs which focused on the effects on model performance of adding NOx emissions from lightning strikes, updating updated biogenic emissions, and using an alternative approach for quantifying transport of ozone and precursor pollutants into the U.S. from international anthropogenic and natural sources. In the 2016v2 modeling the amount of transport from international anthropogenic and natural sources was based on a simulation of the hemispheric version of the Community Multi-scale Air Quality Model (H-CMAQ) for 2016.⁵ The outputs from this hemispheric modeling were then used to provide boundary conditions for national scale air quality modeling at proposal.⁶ Overall, H-CMAQ tends to under-predict daytime ozone concentrations at rural and remote monitoring sites across the U.S. during the spring of 2016 whereas the predictions from the GEOS-Chem global

In: Steyn DG, Trini S (eds) Air 3 pollution modeling and its applications, XXI. Springer, Dordrecht, pp 175–179, 2012.

⁶ Boundary conditions are the concentrations of pollutants along the north, east, south, and west boundaries of the air quality modeling domain. Boundary conditions vary in space and time and are typically obtained from predictions of global or hemispheric models. Information on how boundary conditions were developed for the final rule modeling can be found in the AQM TSD.

model⁷ were generally less biased.⁸ During the summer of 2016 both models showed varying degrees of over prediction with GEOS-Chem showing somewhat greater over-prediction, compared to H-CMAQ. In view of those results, EPA examined the impacts of using GEOSChem as an alternative to H-CMAQ for providing boundary conditions for the final rule modeling.

For the lightning NOx, biogenics, and GEOSChem sensitivity runs, the EPA reran 2016v2 using each of these alternative inputs, individually. Results from these sensitivity runs indicate that each of the three updates provides an improvement in model performance. However, by far the greatest improvement in modeling performance is attributable to the use of GEOSChem. In view of these results the EPA has included lightning NOx emissions, updated biogenic emissions, and international transport from GEOSChem in the 2016v3 modeling used for this final action. As described in Appendix B, the model has less bias and error regionally and at individual nonattainment/maintenance receptors on high ozone days using these updates.

2016 Model Performance Sensitivity Analysis

1

Bias (ppb) in MDA8 Ozone by Day – 2016v2 Modeling

Modeling Platform Updates Examined to Address Model Performance Concerns

- Initial & Boundary Concentrations: Use GEOSChem rather than Hemispheric CMAQ (H-CMAQ) to provide initial and boundary concentrations for the outer (36 km) modeling domain. (GEOSChem => 36US3 => 12US2 domain)
- <u>Biogenic Emissions</u>: Use a recently released updated version of BEIS + BELD land use (BEIS4/BELD6) which includes state-of-science emissions factors and improved land use data

 <u>Lightning NOx</u>: Include 3-D NOx emissions from lightning strikes using a soon-to-be published method developed by ORD.

Sensitivity Model Runs to Explore Impacts of Potential Updates

- Model Runs for 2016
 - 1) GEOSChem for initial and boundary concentrations
 - 2) BEIS4/BELD6 Biogenics
 - 3) Include emissions of Lightning NOx
 - 4) GEOSChem + BEIS4/BELD6 + Lightning NOx
- Model Run for 2023
 - 5) GEOChem for projected 2023 design values and contributions

Model Performance Evaluation for 2016v3 Base Year CAMx Simulation

I. Introduction

An operational model evaluation was conducted for the 2016v3 base year CAMx v7.10 simulation performed for the 12 km U.S. modeling domain. The purpose of this evaluation is to examine the ability of the 2016 air quality modeling platform to represent the magnitude and spatial and temporal variability of measured (i.e., observed) maximum daily average (i.e., MDA8) ozone concentrations within the modeling domain. The evaluation presented here is based on model simulations using the 2016v3 emissions platform (i.e., scenario name 2016gf). As part of this evaluation we compare model performance for the 2016v3 platform to model performance for the 2016v2 platform that used for the proposed disapproval actions.

The model evaluation for ozone focuses on comparing 8-hour daily maximum (i.e., MDA8) ozone concentrations to the corresponding observed data at monitoring sites in the EPA Air Quality System (AQS). The locations of the ozone monitoring sites in this network are shown in Figure B-1.

This evaluation includes statistical measures and graphical displays of model performance based upon model-predicted versus observed concentrations. The evaluation focusses on model predicted and observed MDA8 ozone concentrations that were paired in space and time. Model performance statistics were calculated for several spatial scales and temporal periods. Statistics were calculated for individual monitoring sites and in aggregate for monitoring sites within each of the nine climate regions of the 12 km U.S. modeling domain. The regions include the Northeast, Ohio Valley, (Upper) Midwest, Southeast, South, Southwest, Northern Rockies, Northwest and West^{1,2}, which are defined based upon the states contained within the

¹ The nine climate regions are defined by States where: Northeast includes CT, DE, ME, MA, MD, NH, NJ, NY, PA, RI, and VT; Ohio Valley includes IL, IN, KY, MO, OH, TN, and WV; Midwest includes IA, MI, MN, and WI; Southeast includes AL, FL, GA, NC, SC, and VA; South includes AR, KS, LA, MS, OK, and TX; Southwest includes AZ, CO, NM, and UT; Northern Rockies includes MT, NE, ND, SD, WY; Northwest includes ID, OR, and WA; and West includes CA and NV.

² Note most monitoring sites in the West region are located in California (see Figures B-1 and B-2), therefore the statistics for the West region will be mostly representative of model performance in California ozone.

National Oceanic and Atmospheric Administration (NOAA) climate regions (Figure B-2)³ as defined in Karl and Koss (1984).

II. Methodology

Model performance statistics were created for the period May through September (i.e., seasonal) and for individual months during this time period. Statistics were created using data on all days with valid observed data during this period as well as for the subset of days with observed MDA8 concentrations ≥ 60 ppb.⁴ The aggregate statistics by climate region and for the monitor plus modeled 2023 receptors are presented in this appendix. Model performance statistics for MDA8 ozone at individual monitoring sites nationwide based on days with observed values ≥ 60 ppb can be found in the docket in the file named "2016v3 CAMx Ozone Model Performance Statistics by Site".

In addition to the above performance statistics, we prepared several graphical presentations of model performance for MDA8 ozone. These graphical presentations include: (1) maps that show the mean bias and error as well as normalized mean bias and error calculated for MDA8 \geq 60 ppb for May through September at individual monitoring sites; (2) maps that show the change in bias and error in the 2016v3 modeling compared to the 2016v2

modeling;

(2) bar and whisker plots that show the distribution of the predicted and observed MDA8 ozone concentrations by month (May through September) and by region; and

(3) time series plots (May through September) of observed and predicted MDA8 ozone concentrations for each region and for a selected set of monitoring sites that are projected to be nonattainment or maintenance-only receptors in 2023.

The Atmospheric Model Evaluation Tool (AMET) was used to calculate the model performance statistics used in this document (Gilliam et al., 2005). For this evaluation we have selected the mean bias, mean error, normalized mean bias, and normalized mean error to

³ NOAA, National Centers for Environmental Information scientists have identified nine climatically consistent regions within the contiguous U.S., http://www.ncdc.noaa.gov/monitoring-references/maps/us-climate-regions.php.

⁴ We limited the data to those observed and predicted pairs with observations that are ≥ 60 ppb in order to focus on concentrations at the upper portion of the distribution of values.

characterize model performance, statistics which are consistent with the recommendations in Simon et al. (2012) and EPA's photochemical modeling guidance (U.S. EPA, 2018).

Mean bias (MB) is the average of the difference (predicted – observed) divided by the total number of replicates (n). Mean bias is given in units of ppb and is defined as:

$$MB = \frac{1}{n} \sum_{1}^{n} (P - O)$$
, where P = predicted and O = observed concentrations

Mean error (ME) calculates the absolute value of the difference (predicted - observed) divided by the total number of replicates (n). Mean error is given in units of ppb and is defined as:

$$\mathrm{ME} = \frac{1}{n} \sum_{1}^{n} |P - O|$$

Normalized mean bias (NMB) is the average the difference (predicted - observed) over the sum of observed values. NMB is a useful model performance indicator because it avoids over inflating the observed range of values, especially at low concentrations. Normalized mean bias is given in percentage units and is defined as:

NMB =
$$\frac{\sum_{1}^{n} (P-O)}{\sum_{1}^{n} (O)} * 100$$

Normalized mean error (NME) is the absolute value of the difference (predicted - observed) over the sum of observed values. Normalized mean error is given in percentage units and is defined as:

NME =
$$\frac{\sum_{1}^{n} |P-O|}{\sum_{1}^{n} (O)} * 100$$

III. Overview of Findings

As described in more detail below, the model performance statistics indicate that the MDA8 ozone concentrations predicted by the 2016v2 CAMx modeling platform closely reflect the corresponding MDA8 observed ozone concentrations in each region of the 12 km U.S. modeling domain. The acceptability of model performance was judged by considering the 2016v2 CAMx performance results in light of the range of performance found in recent regional ozone model applications (Emery et al., 2017; NRC, 2002; Phillips et al., 2007; Simon et al.,

2012; U.S. EPA, 2005; U.S. EPA, 2009; U.S. EPA, 2010).⁵ These other modeling studies represent a wide range of modeling analyses that cover various models, model configurations, domains, years and/or episodes, chemical mechanisms, and aerosol modules. In particular, Emery et.al. extend the results of Simon et.al., to include performance results from a few more recent photochemical model applications. The results in the former paper indicate that about a third of the top performing past applications have normalized mean bias and a normalized mean error statistics for MDA8 ozone of less than ± 5 percent and less 15 percent, respectively. In addition, two-thirds of past applications have normalized mean bias less than ± 15 percent and normalized mean error less than 25 percent. These "benchmarks" are not intended to represent "rigid pass/fail tests" but rather as "simple references to the range of recent historical performance" that can be used to understand where the performance results of a particular application "fall in the spectrum of past published results."

Overall, the ozone model performance results for the 2016v2 CAMx simulation are in large part within the range found in other recent peer-reviewed and regulatory applications. The model performance results, as described in this document, demonstrate that the predictions from the 2016v2 modeling platform correspond closely to observed concentrations in terms of the magnitude, temporal fluctuations, and geographic differences for MDA8 ozone concentrations.

IV. Analysis of Model Performance Statistics and Graphics

The MDA8 ozone model performance bias and error statistics for the period May-September for each climate region are provided in Table B-1. The statistics shown in this table were calculated using all data pairs for May-September. Seasonal statistics for each region based on the subset of days with observed MDA8 ozone ≥ 60 ppb are presented in Table B-2. Seasonal statistics at each receptor on days with observed MDA8 ozone ≥ 60 ppb are presented in Table B-3 for the 2016v3 and 2016v2 modeling.

Spatial plots of the mean bias and error as well as the normalized mean bias and error at individual monitors nationwide are shown in Figures B-3 through B-8. Time series plots of observed and predicted MDA8 ozone during the period May through September for each region and for selected 2023 nonattainment and/or maintenance sites in 2023 are provided in Figures B-9 and B-10, respectively.

CIRCLE=AQS_Daily;

A. Seasonal and Monthly Performance

1. Model Performance Statistics by Region

The model performance statistics provided in Table B-1 show that regional mean tends to overpredict in most regions on average for all days during the period May through September in each region. Normalized mean bias is less than \pm 5 percent in the Midwest, Southwest, Northern Rockies, Northwest, and West. In the other four regions, normalized mean bias is between 5 and 15 percent. Normalized mean error is less than 15 percent in the Midwest, Southwest, Northern Rockies, and West and between 15 and 20 percent in the other regions.

The model performance statistics for days with observed MDA8 ozone ≥ 60 ppb provided in Table B-2 indicates that, on average, the model is relatively unbiased in all regions. The seasonal mean bias for MDA8 ozone ≥ 60 ppb is within ± 5 ppb in six of the regions and within ± 10 ppb in the other three regions. The mean error is less than 10 ppb in all regions. Normalized mean bias is within 10 percent for all regions, except for the West where the normalized mean bias is -11.5 percent. The normalized mean error is less than 15 percent in each region.

The model performance statistic for individual receptors in Table B-3 indicates improved performance in the 2016v3 modeling compared to the 2016v2 modeling. The 2016v3 modeling has significantly less bias and error on days with observed MDA8 ozone \geq 60 compared to the 2016v2 modeling at all receptors, except for the Greenwich and Houston/Clinton. The normalized mean bias and normalized mean error statistics are within the performance benchmarks identified above.

2. Spatial Variability in Model Performance

Figures B-3 through B-6 show the spatial variability in bias and error for MDA8 ozone on days with observed concentrations ≥ 60 ppb. Mean bias, as seen in Figure B-3, is within ± 5 ppb at many sites nationwide. The 2016v3 modeling tends to overpredict MDA8 concentrations on days ≥ 60 ppb in parts of the Southeast, Ohio Valley, and mid-Atlantic states. Biases within the range of ± 5 ppb or between -5 and -10 ppb are noted at monitoring sites elsewhere across the U.S. Figure B-4 provides a comparison of the mean bias in the 2016v3 modeling to the mean bias in the 2016v2 modeling. The figure indicates that model performance for days ≥ 60 ppb is improved at most monitoring sites nationwide, the exceptions are some of the monitoring sites in the Southeast and mid-Atlantic states. As is evident from Figure B-5, the mean error is mainly less than 10 ppb nationwide. The comparison of mean error between the 2016v3 modeling and the 2016v2 modeling, as shown in Figure B-6, shows improved performance in terms of model error with the 2016v3 modeling.

The normalized mean error on days > 60 ppb, as shown in Figure B-7, indicates that model performance using this statistic is within the range of the performance benchmark offered by Emery et al (i.e., \pm 15 %) at nearly all monitoring sites. The normalized mean bias and mean bias statistics suggest a tendency for some over prediction by the model in portions of the South, Southeast, and Northeast regions. As indicated in Figure B-8, normalized mean error is less than the 25 percent benchmark at nearly all monitoring sites nationwide.

B. Observed and Predicted Temporal Patterns

In addition to the above analysis of overall model performance, we also examine how well the 2016v3 modeling platform replicates day to day fluctuations in observed MDA8 ozone concentrations for the period May through September in each region and for selected 2023 nonattainment and/or maintenance receptors.

Time series of regional average MDA8 ozone concentrations for the Northeast, Midwest, Ohio Valley, South, Southeast, Southwest, and West regions are provided in Figure B-9. The plots show that the modeled concentrations closely track the corresponding observed values in terms of day-to-day fluctuations and the general magnitude of concentrations. Comparing the

B-8

plots for these seven regions reveals that there are large differences in the day-to-day variability among the regions in both observations and predictions. For example, the degree of temporal variability in MDA8 ozone concentrations in the Northeast, Midwest, and Ohio Valley is much greater than in the Southwest and West. As is evident from Figure B-9, the modeling platform captures regional differences in the degree of temporal variability in MDA8 ozone concentrations. The model performs equally as well in eastern and western regions in terms of replicating the relative magnitude of concentrations and day-to-day variability that are characteristic of observed MDA8 ozone concentrations in each region.

The time series for selected receptors indicate that, again, the modeling platform generally replicates the day-to-day variability in ozone during this time period at these sites.⁶ That is, days with high modeled concentrations are generally also days with high measured concentrations and, conversely, days with low modeled concentrations are also days with low measured concentrations in most cases. Although there is a tendency for over prediction, particularly on days with low measured ozone concentrations, the model predictions, as illustrated by these receptors, captures the day-to-day variability in the observations, and also generally the timing and relative magnitude of multi-day high ozone episodes. In this regard, the model captures the geographic differences in the timing, duration, and general magnitude of ozone episodes in different parts of the U.S.

At the Stratford and Madison receptors in Coastal Connecticut, the model closely replicates both the day-to-day variability and magnitude of the observed MDA8 ozone concentrations on most days. At the Chicago-Northbrook and Chicago-Evanston receptors, the model closely tracks the day-to-day variability during the entire 5-month period. At both receptors, the modeled concentrations are similar to the corresponding measured. At the Kenosha-Chiwaukee and Sheboygan monitors the model captures the high ozone episodes, but under predicts peak MDA8 ozone concentrations of several of the days with the highest concentrations, particularly at the Sheboygan receptor. At the Dallas/Denton, Houston, and Brazoria receptors the temporal pattern in the observed values appears to be rather "chaotic", compared to the temporal pattern at other receptors in the eastern U.S. The model predictions have a temporal pattern that is similar to the observed concentrations, but with a tendency for

⁶ The extent to which the day-to-day variability in model-predicted MDA8 ozone matches the corresponding observations values at the receptors selected for Figure B-9 is generally representative of most other receptors within the same areas.

overprediction. In contrast to receptors in the East, the observed concentrations at receptors in the West have much less temporal variability. This difference between the observed concentrations in the East versus the West is well simulated by the model. Although the model appears to capture most of the days with high ozone at the receptors in Denver, there is a tendency for the model to under predict on the peak days at receptors in Salt Lake City.

C. Conclusions

In summary, the ozone model performance statistics for the CAMx 2016v3 (2016gf) simulation are within or close to the ranges found in other recent peer-reviewed applications (e.g., Simon et al, 2012 and Emory et al, 2017). As described in this appendix, the predictions from the 2016v3 modeling platform generally correspond closely to observed concentrations in terms of the magnitude, temporal fluctuations, and geographic differences for MDA8 ozone concentrations. Thus, the model performance results demonstrate the scientific credibility of our 2016v3 modeling platform. These results provide confidence in the ability of the modeling platform to provide a reasonable projection of expected future year ozone concentrations and contributions.

Ozone Contributions to Nonattainment & Maintenance-Only Receptors in 2023 The tables in this appendix provide projected design values and contribution metric data from each state and the other source tags to nonattainment and maintenance-only in 2023. Highlighted values denote contributions greater than or equal to the 1 percent of the NAAQS screening threshold. The contributions and design values are in units of ppb. Contributions to individual monitoring sites is provided in the file: "2016v3_DVs_state_contributions" which can be found in the docket for this final action.

Design Values and Contributions for Violating Monitor Receptors in 2023 – Part 2

This page is intentionally left blank

Appendix D Upwind State Collective Contribution in 2023 This appendix provides the 2023 average design values, "home state" contributions, total contributions from all upwind states, and the total upwind contribution expresses as a percent of total ozone (i.e., the 2023 average design value) at each receptor (ppb).

			2023 Average	Home State	Upwind State	Upwind Contribution as a Percent of 2023
