The Safe Drinking Water Act requires that proposed regulations for our drinking water systems demonstrate a "meaningful opportunity for health risk reduction," which means evaluating risk to the public based upon clear exposure and health impact information. As of today, expert toxicologists' opinions and advisory levels for PFAS vary by over 100,000 -fold, indicating that there is no consensus regarding the toxicity of these compounds at drinking water levels. Numerous toxicologists, epidemiologists, and risk assessors worldwide have disagreed with the U.S. EPA technical review of PFOA and PFOS toxicity data. For example, the U.S. EPA's proposed strategy for regulating PFOA and PFOS as carcinogens with an MCL Goal of zero is in direct contrast with the United Kingdom's independent science advisory committee conclusion that there is "no evidence for a link between exposure to PFASs and cancer risk." (COT, 2022, p. 24). Additionally, all the noncancer health endpoints used by the U.S. EPA are based on "suggestive" evidence only; there is still no clear evidence that exposure to low levels of PFAS causes any human disease. We ask that the U.S. EPA take a more balanced approach to their interpretations of the potential human health risks associated with PFAS, consistent with

international agencies that have developed more practical approaches that consider the significant uncertainties within the available toxicity data.

EPA Response: The EPA disagrees that the available data do not support the determination that PFOA and PFOS are *Likely to Be Carcinogenic to Humans*. Please see section 4.1.4 of the EPA response in this *Response to Comments* document regarding the EPA's determinations that PFOA and PFOS are *Likely to Be Carcinogenic to Humans* in accordance with the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) and section 4.2.6 of the EPA response in this *Response to Comments* document regarding differences between the EPA's conclusions in the toxicity assessments for PFOA and PFOS and the conclusions of other health agencies. Please see the EPA response to comments Doc. #1774, SBC-053196, SBC-053187, SBC-053190 in section 4.1.4.2 and the EPA response to comment Doc. #1774, SBC-045184 in section 1.2 in this *Response to Comments* document for more detailed discussion on the cancer classification and studies supporting the EPA's conclusions for PFOS and the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683 in section 4.1.4.3 in this *Response to Comments* document for more detailed discussion on the cancer classification and studies supporting the EPA's conclusions for PFOA. As noted in that response, the EPA's determinations were supported by the EPA's Science Advisory Board (USEPA, 2022b), among others. Please see section 4.2.2 of the EPA response in this *Response to Comments* document for rebuttals to the incorrect claim that all of the noncancer health endpoints are based on "suggestive" evidence only. As described further in that section and in Section 3.4 of the PFOA and PFOS toxicity assessments (USEPA, 2024d; USEPA, 2024c), the EPA determined that the available *evidence indicates* there are likely associations between PFOA or PFOS and effects on the four prioritized noncancer health outcomes (i.e., developmental, hepatic, cardiovascular, and immune).

Association of Metropolitan Water Agencies (AMWA) (Doc. #1738, SBC-053386)

Cancer

While EPA cites multiple lines of evidence to support its carcinogenic finding, this section compares different agencies' conclusions concerning the epidemiologic evidence. Two studies involving participants in the C8 Health Project showed a positive association between PFOA levels (mean at 24 ng/mL) and kidney and testicular cancers [FN40: Vaughn Barry, Andrea Winquist, and Kyle Steenland, "Perfluorooctanoic Acid (PFOA) Exposures and Incident Cancers among Adults Living near a Chemical Plant," Environmental Health Perspectives, 2013.]. The C8 Science Panel concluded that a probable link existed between PFOA exposure and testicular and kidney cancer [FN41: C8 Science Panel, "C8 Probable Link Reports," 2012.].

In an occupational study in Italy, statistically significant increases in liver cancer mortality, malignant neoplasms of the lymphatic and hematopoietic tissue, and in all malignant neoplasms with cumulative serum PFOA exposure greater than 16,956 ng/mL-years. In another occupational study based on a West Virginia DuPont cohort, no significant associations with

incidence of cancers of the bladder, colorectal, prostate, and melanoma were observed when compared to the general population [FN42: Kyle Steenland and Susan Woskie, "Cohort Mortality Study of Workers Exposed to Perfluorooctanoic Acid," American Journal of Epidemiology, November 2012.].

Fifteen epidemiological and one animal toxicological study that investigated the association between PFOS and cancer were identified. Although the epidemiological evidence found mixed results across tumor types, EPA says that the available study findings support a plausible correlation between PFOS exposure and carcinogenicity in humans.

PFOS was associated with an increased risk of kidney cancer in a medium confidence study [FN43: Joseph Shearer et al., "Serum Concentrations of Per- and Polyfluoroalkyl Substances and Risk of Renal Cell Carcinoma," Journal of the National Cancer Institute, 2021.]. A case-control study within the National Cancer Institute's Prostate, Lung, Colorectal, and Ovarian Screening Trial reported a statistically significant positive trend in risk of renal cell carcinoma with pre-diagnostic PFOS serum levels.

One study also observed statistically significant increased odds of ovarian cancer both per ng/mL increase in PFOS and in the two highest quartiles of exposure, although the association was significantly inverse for the second quartile of PFOS exposure [FN44: Ogbedor Omoike et al., "Association between per and Polyfluoroalkyl Substances and Markers of Inflammation and Oxidative Stress," Environmental Research, May 2021.].

The evidence database for the carcinogenicity of PFOS is comprised of several epidemiological studies and a single chronic cancer. The available epidemiology studies report elevated risk of bladder, prostate, kidney, and breast cancers after chronic PFOS exposure. However, EPA notes that the study designs, analyses, and mixed results do not allow for a definitive conclusion on the relationship between PFOS exposure and cancer outcomes.

EPA explains that the low confidence sources are limited by selection bias, and confounders specific for cancer outcomes, including smoking and socioeconomic factors, were not addressed and behavioral risk factors could have differed. The EFSA, HC, and the WHO do not find the epidemiology evidence robust enough to support a causal link between PFOA exposure and cancer (see Table 38 and Table 39 in Appendix B).

In summary, since other competent public health agencies have reviewed the same scientific literature as EPA and have reached different conclusions on the existence and the strength of the associations between PFOS and PFOA exposure and disease, EPA must take this uncertainty into account. EPA must do so in a quantitative, reproducible uncertainty analysis as required by Circular A-4. Providing the range of potential benefits will also increase the public's understanding of the regulatory options.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document. The EPA followed the agency's *Guidelines for Carcinogen Risk Assessment* in making its cancer determinations for PFOA (USEPA, 2005) and the EPA directs

the commenter to Section 3.5.5 of the toxicity assessments (USEPA, 2024d; USEPA, 2024c) which details the weight of evidence for PFOA and PFOS, and the EPA's rationale for ultimately determining PFOA and PFOS are *Likely to Be Carcinogenic to Humans* (USEPA, 2005).

The commenter points to the conclusions of other authoritative agencies (i.e., European Food Safety Authority (EFSA), the World Health Organization [WHO], Health Canada [HC]) and stated that they did "not find the epidemiology evidence robust enough to support a causal link between PFOA exposure and cancer." The EPA disagrees with the commenter that the conclusions cited differ from the EPA's conclusions. In fact, the EPA agrees that there is not adequate evidence from epidemiological studies supporting a causal association between PFOA exposure and increased cancer risk in humans. This is evident in the EPA's selection of the *Likely to Be Carcinogenic to Humans* cancer descriptor for PFOA (see Section 3.5.5; USEPA, 2024d) rather than the *Carcinogenic to Humans* descriptor (see Section 5.4; USEPA, 2024d). The EPA has clearly stated that, "[a] plausible, though not definitively causal, association exists between human exposure to PFOA and kidney and testicular cancers," in humans. The EPA makes similar conclusions regarding the lack of evidence from epidemiological studies supporting a causal relationship between PFOS exposure and cancer risk (USEPA, 2024c).

As described in the EPA's response to comments received on quantified uncertainties in the economic analysis (see section 13.9 of the EPA response in this *Response to Comments* document), the EPA assessed all major sources of uncertainty in the EA using both quantitative and qualitative approaches which is consistent with OMB Circular A-4 guidance. For some key sources of uncertainty, including model inputs for health effect exposure response slope factors, the EPA quantitatively assessed the uncertainty by evaluating the distribution of values for those inputs. See section 13.9 of the EPA response in this *Response to Comments* document, Chapter 6 of the EA (USEPA, 2024f), and section XII of the FRN for additional details on the EPA's uncertainty analysis and the presentation of uncertainty analysis results.

4.1.4.2 Comments Specific to PFOS

AWWA (Doc. #1759, SBC-045598)

As with PFOA, EPA is proposing to establish a MCLG of zero (0 ppt) for PFOS following a determination that PFOS is suggestive to be carcinogenic. As noted in comments in 2021, AWWA supports this determination (AWWA, 2021a). If EPA moves forward with a conclusion that PFOA is carcinogenic, AWWA agrees that the appropriate MCLG for a carcinogen is 0 ppt (zero).

EPA Response: In the proposed rule, the agency stated that PFOS is *Likely to Be Carcinogenic to Humans* in accordance with the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) and therefore, the EPA set the proposed MCLG for PFOS at zero. The commenter mistakenly stated that "PFOS is suggestive to be carcinogenic," but agreed with the EPA's determination that an MCLG of zero is appropriate.

3M Company (Doc. #1774, SBC-045684)

ii. PFOS

The agency's conclusion that PFOS is likely to be carcinogenic to humans is likewise undermined by the lack of a reliable process for identifying and evaluating available evidence. As a result, EPA's conclusion is inconsistent with the evidence that EPA presents, as well as with fundamental scientific principles. In its November 2021 draft PFOS MCLG document submitted to SAB, EPA said there was "suggestive evidence of carcinogenic potential" of PFOS in humans. Now, without providing adequate justification, the Agency has switched its carcinogenicity determination for PFOS despite no new evidence and came to different conclusions about studies it had previously reviewed. The vast majority of the studies that EPA produced and analyzed reported no effects, no effects of statistical significance, or effects that are inapplicable for human risk assessment because of species differences. EPA's conclusion that the weight of evidence supports the classification that PFOS is likely to be carcinogenic to humans is inconsistent with the weight of the evidence to the contrary, as further detailed in this section Of critical importance, the PFOS cancer assessment as written was not reviewed by the SAB, counter to the Cancer Guidelines (USEPA 2005) that state, "[g]enerally, cancer risk decisions strive to be "scientifically defensible, consistent with the agency's statutory mission, and responsive to the needs of decision-makers" (NRC, 1994). Scientific defensibility would be evaluated through use of EPA's Science Advisory Board, EPA's Office of Pesticide Programs' Scientific Advisory Panel, or other independent expert peer review panels to determine whether a consensus among scientific experts exists." EPA's conclusions on the carcinogenicity of PFOS have been proposed without sufficient peer review, in violation of EPA's own Cancer Guidelines.

EPA Response: The EPA disagrees with the claim that the EPA's analyses and conclusions are inconsistent with either the evidence the EPA presents or fundamental scientific principles. As discussed throughout the administrative record and consistent with the SDWA, the EPA disagrees that there was a "lack of a reliable process" used to develop the toxicity assessments for PFOA and PFOS; the EPA has identified and used the best available, peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices and data collected by accepted methods or best available methods and considered internal review and external peer-review input in reaching conclusions (see sections 4.1.2 and 4.1.3 of the EPA response in this *Response to Comments* document). The commenter incorrectly suggests that the cancer assessment provided in the public comment draft toxicity assessment was not reviewed by the SAB and therefore lacks sufficient peer review. In fact, the SAB did review and comment on the cancer assessment as evidenced by the SAB's recommendation that the EPA provide an "explicit description of why the available data for PFOS do not meet the EPA *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) criterion for the higher designation as 'likely carcinogenic'" and that the EPA was "overly conservative in dismissing the appearance of a dose-response relationship for [hepatocellular carcinoma], particularly in females…Given that multiple MOAs may be operative in this outcome, the Panel suggests that the EPA reevaluate the 2012 Butenhoff study" actually prompted the EPA's

reevaluation of the available data and subsequent reclassification of PFOS as *Likely to Be Carcinogenic to Humans* (USEPA, 2022b). During its reevaluation of the data, following the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005), the EPA concluded that the available data for PFOS do in fact surpass the designation of *Suggestive Evidence of Carcinogenicity*. The commenter also incorrectly stated that the EPA did not provide adequate justification for this revision to the cancer descriptor. In fact, a thorough description of the rationale for this determination can be found in Sections 3.5 and 5.4 of the final toxicity assessment (USEPA, 2024c) and sections 3.5 and 6.4 of the *Proposed MCLG* documents (USEPA, 2023a) available for public comment. Further, 68dditionditional epidemiological cancer studies included in the final toxicity assessment, which post-dated the SAB review, add to the weight of the evidence for carcinogenicity and strengthen the conclusion that PFOS is *Likely to Be Carcinogenic to Humans* (i.e., Goodrich et al., 2022 and Cao et al., 2022) as described below. The four overarching factors that the EPA used to support the decision to update the cancer descriptor for PFOS are presented in section 4.1.4 of the EPA response in this *Response to Comments* document. For responses regarding SDWA's requirements for SAB comment prior to proposal, see section 4.3.2 of the EPA response in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053187)

B. Epidemiological Evidence

EPA is inconsistent in its presentation of epidemiological data regarding PFOS (USEPA 2023c). [FN64: EPA stated that it "identified 15 epidemiological" studies, of which "8 were classified as medium confidence, 6 as low confidence, and 1 was considered uninformative" (p. 3-260). In another section (p. 3-263), the agency states that, "of the 15 studies identified since the 2016 assessment (Figure 3-73), seven were considered medium confidence and six were low confidence," and that figure shows two studies as critically deficient.] EPA summarized epidemiological studies regarding PFOS and their reliability in USEPA (2023c). In a previous assessment that EPA conducted of pre-2016 epidemiology studies of PFOS for its 2016 Health Effects Support Document for PFOS (USEPA 2016), [FN65: See (USEPA 2023c at Figure 3-72, p. 3-262).] EPA concluded that Jørgensen (2011), Eriksen (2009) and Grice (2007) did not support EPA's new conclusion in the proposed NPDWR regarding PFOS carcinogenicity. [FN66: See (USEPA 2023c at 3-260-261).] Nonetheless, in EPA's weight-of-evidence conclusion for carcinogenicity, the agency misleadingly stated that Grice (2007) "observed that prostate cancers were among the most frequently reported malignancies." This directly contradicts the original authors' conclusions that they "observed no association between working in a PFOS-exposed job and several cancers, common health conditions, and birth weight" (Grice 2007).

The majority of the studies Identified by EPA as relevant for assessing whether PFOS is carcinogenic concluded no, or in one case, even a reduced risk of cancer from PFOS exposure, as follows:

· Bonefeld-Jørgensen et al. (2011): "the association was of a low magnitude and could not be separated from the effects of other perfluorosulfonated compound exposures" (p. 3- 283).

· Cohn et al. (2020):" maternal PFOS was associated with a decreased daughters' breast cancers risk" (p. 3-265).

· Ducatman et al. (2015): "No association between PFOS exposure and prostate cancer was reported […] in a study of the association between PFOS serum concentrations and prostate specific antigen (a biomarker of prostate cancer)" (p. 3-282).

· Eriksen et al. (2009): "No elevated bladder cancer risk was observed in a nested casecontrol study in a Danish cohort" (p. 3-261).

· Fry and Power (2017): "Cancer mortality based on Public-use Linked Mortality Files was not associated with PFOS exposure" (p. 3-266).

· Grice et al. (2007): "they did not reach statistical significance" (p. 3-261).

· Hurley et al. (2018):" A nested case-control study did not observe an association between breast cancer identified through California cancer registry and PFOS concentrations in serum" (p. 3-265).

· Shearer et al. (2021): "reported a statistically significant positive trend in risk of renal cell carcinoma" but "the association with PFOS was attenuated after adjusting for other PFAS […]. There was no association when evaluated on a per doubling of PFOS after adjusting for other PFAS" (p. 3-265).

In particular, there is a lack of confidence in EPA's review methodology, especially as it relates the Eriksen et al. (2009) study when compared to the Shearer et al. (2021) study. Both studies used the same methodology during the same time period. Both studies were published in the Journal of the National Cancer Institute. The Shearer et al. study originated from the PLCO screening trial study that enrolled approximately 150,000 individuals. These participants were enrolled between 1993 – 2001. Single measurement blood (serum) samples were collected at enrollment. At a later date, these samples were measured for PFOA and PFOS. A case control study was much later conducted of those who subsequently were diagnosed with kidney cancer (324 cases, 324 controls) and their archived serum sample for PFOS and PFOA. The Eriksen study originated from the prospective cohort Danish Diet, Cancer, and Health Study which had a cohort of 57,053 individuals aged 50 -65 years, born in Denmark with no previous cancer diagnoses. These participants were enrolled between 1993 – 1997. As with Shearer et al., there was only a single measure of blood (plasma) taken for each participant. Eriksen et al. followed the cancer experience in this cohort through mid-2006. Cases were ascertained through the Danish National Cancer Registry. A total of 713 prostate cancer cases, 332 bladder cancer cases, 128 pancreatic cancer cases, and 67 liver cancer cases were identified in this follow-up time period. A total of 772 noncancer cases were selected as controls. Archived plasma samples were measured for PFOA and PFOS. Eriksen concluded there was no clear differences in risk for these cancers in relation to plasma concentrations of PFOA and PFOS.

Unlike Shearer et al. (who assert that a single measurement can be used), however, Eriksen et al. wrote, "Consequently, misclassification may have occurred because the concentration may have occurred because the concentration at one moment in time may not reliably reflect the relevant plasma concentrations decades ago or at other times." Eriksen is the largest study, to date, to examine prostate, pancreas, and especially liver cancer, in the general population with PFOS exposure. (The Eriksen et al. study also analyzed for serum PFOA concentrations).

EPA judged both studies by Shearer et al. and Eriksen et al. to result in overall "adequate" confidence with confounding to be deficient in both studies (i.e., both had the same qualitative measurements for cigarette smoking). Given the same methodology, EPA considered Shearer et al. to have good metric scores for participant selection, exposure measurement, outcome, and analysis, whereas Eriksen et al. only received one good metric for participant selection. The mere fact that the EPA has considered PFOS to be likely carcinogenic (based on liver cancer in rats) but utterly failed to mention the Eriksen et al. study for its null liver cancer results in the PFOS final report illustrates inconsistency and apparent arbitrariness EPA's carcinogenicity assessment process.

In conclusion, EPA's process errors led it to reach a carcinogenicity determination that is contrary to the weight of epidemiological evidence in violation of EPA's own Cancer Guidelines.

EPA Response: As discussed throughout the administrative record and consistent with the SDWA, the EPA disagrees that there were process issues related to the development of the toxicity assessments for PFOA and PFOS; the EPA has identified and used the best available, peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices and data collected by accepted methods or best available methods and considered internal review and external peer-review input in reaching conclusions (see sections 4.1.2 and 4.1.3 of the EPA response in this *Response to Comments* document).

The commenter additionally stated several perceived issues with the epidemiological evidence presented to support the cancer classification for PFOS. First, the commenter points out a minor discrepancy in the study count for each confidence level between Sections 3.5 and 3.5.1.2 of the draft toxicity assessment (USEPA, 2023a). In response to this comment, the EPA has updated the confidence level counts to match Figure 3-74, including the addition of both studies identified in the updated 2023 literature search (Goodrich et al., 2022; Cao et al., 2022), which underwent systematic review steps and were included in the cancer synthesis of the final PFOS toxicity assessment (USEPA, 2024c, section 3.5).

Second, the commenter incorrectly claimed that the EPA mischaracterized study conclusions from Grice (2007) and raised additional concerns about studies evaluating associations between exposure to PFOS and cancer, citing studies that reported no association between PFOS exposure and cancer. The EPA disagrees that it mischaracterized the conclusions of Grice et al. (2007). Grice et al. (2007) reports non-significant but positive associations between PFOS and prostate cancer, and the author directly states "[m]elanoma (n=39), prostate cancer (n=29), and colon cancer (n=22) were the most frequently reported malignancies on the questionnaire." The EPA

maintains its position based on the publication's summary that prostate cancer was one of the most frequently reported cancers and disagrees that this statement contradicts the study publication's other conclusions that there was no statistically significant association between PFOS exposure and various cancer incidences; these two facts are not mutually exclusive. Additionally, a finding that lacks statistical significance can be used to support a conclusion of an effect (Wasserstein and Lazar, 2016; USEPA, 2022a); other factors, such as biological significance of the observed effect, also contribute to the EPA's conclusions regarding the effect.

The commenter also mistakenly combines results from multiple epidemiological studies assessing different target organs and cancer types (e.g., bladder, liver, prostate, breast) and also disregards study evaluation results to overstate null results observed in the PFOS epidemiological evidence stream. Critically, null results reported in one tumor site or study does not negate positive results reported in other tumor sites or studies. As stated in the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005), "Null results from epidemiologic studies alone generally do not prove the absence of carcinogenic effects because such results can arise either from an agent being truly not carcinogenic or from other factors such as: inadequate statistical power, inadequate study design, imprecise estimates, or confounding factors. Moreover, null results from a well-designed and well-conducted epidemiologic study that contains usable exposure data can help to define upper limits for the estimated dose of concern for human exposure in cases where the overall weight of the evidence indicates that the agent is potentially carcinogenic in humans."

For example, the commenter raised concerns about several studies on breast cancer (Bonefeld-Jørgensen et al., 2011; Cohn et al., 2020; Hurley et al., 2018) without providing further context. The EPA acknowledges evidence for an association between elevated exposure to PFOS and increased risk of breast cancer is mixed; there are factors related to study design that add a degree of uncertainty for this association. Several studies did not consider differences between breast cancer types (Bonefeld-Jørgensen et al., 2011; Cohn et al., 2020), which is especially important in light of other studies that consistently reported significantly increased risk of Progesterone Receptor Positive (PR+) and Estrogen Receptor Positive (ER+) breast cancer with elevated PFOS exposure (Mancini et al., 2020; Tsai et al., 2020). Analyzing all breast cancers combined, regardless of type, can limit specificity and the ability to draw conclusions about coherence between studies. Considering all available breast cancer studies identified by the EPA, five studies (5/13) reported an increased risk of breast cancer, which provides supports conclusions of a potentially increased risk of breast cancer with increasing PFOS exposure, but the overall evidence remains mixed due to study design issues, lack of replication of the results, and a lack of mechanistic understanding of the potential relationship between PFOS and specific breast cancer subtypes. The EPA considered all of these factors and others described in this response and in section 4.1.4 of the EPA response in this *Response to Comments* document, when developing conclusions about the weight of evidence for the carcinogenic potential of PFOS, in addition to statistical significance of the results.

The other studies mentioned by the commenter (Fry and Power, 2017; Ducatman et al., 2015) reported results for cancer outcomes that did not have a significant impact on the conclusion of the assessment. Fry and Power (2017) analyzed mortality due to any cancer type, thus combining all cancer types and providing an estimate of mortality risk that lacks specificity to a specific cancer type. Since the mode of action (MOA) can vary by cancer type, analyzing all-cause cancer mortality may dilute associations for specific types of cancer (e.g., liver or kidney cancer). Ducatman et al. (2015) examined associations between elevated PFAS exposure and changes in prostate-specific antigen (PSA), not incidence of prostate cancer. While PSA has historically been used for prostate cancer screening, Ducatman et al. (2015) acknowledge the complexities of using PSA as a screening tool due to other potential causes of elevated PSA (e.g., prostate hyperplasia, prostate inflammation, urinary retention, local trauma, and age). While the study was well-conducted, the uncertainty related to PSA's specificity as a biomarker of effect for prostate cancer and lack of a specific analysis of the association between elevated PFOS exposure and risk of prostate cancer limited the study's impact on the assessment's conclusions.

Fourth, the commenter raised concerns about and compared the results of Eriksen et al. (2009) and Shearer et al. (2021) to argue that the EPA's methodologies for evaluating studies were flawed. The commenter claimed that those two studies are similar for various reasons but received different ratings for several study evaluation domains: exposure measurement, outcome ascertainment, and analysis. In addition, the commenter mentions characteristics of the studies (such as the journal of publication) that are irrelevant to the risk of bias assessment (USEPA, 2022a). The EPA agrees that the studies are similar in quality, hence the overall determination of *medium* confidence for both. However, the study designs are different (case-control vs. prospective cohort), as is the level of detail reported in the studies that allows the reviewers to assess potential for bias. *Good* ratings are typically given to studies that provide detailed information regarding the domain under evaluation, such that the potential for bias can be thoroughly assessed or inferred (USEPA, 2022a). For example, for the exposure measurement domain, Shearer et al. (2021) provided details on blinding of laboratory staff and inclusion of matched case-control pairs within the same analytical batch to mitigate differences due to potential inter-batch variation, which resulted in a *Good* rating for this domain. For the outcome ascertainment domain, early-stage cases of cancer would be less likely to be missed in Shearer et al. (2021) since the study participants were routinely screened for cancer as a part of the Prostate, Lung, Colorectal, and Ovarian Screening Trial (PLCO) Screening Trial. Unlike Eriksen et al. (2009), the analysis presented in Shearer et al. (2021) also included exploration of non-linearity, stratified and sensitivity analyses, and an analysis including only those without evidence of diminished kidney function.

Finally, the commenter stated that the EPA failed to mention the null liver cancer results reported by Eriksen et al. (2009). While results from Eriksen et al. (2009) were generally imprecise, other evidence has since been identified supporting associations between PFOS serum concentrations and liver cancer in humans (i.e., Goodrich et al. (2022) and Cao et al. (2022)), thus also supporting the assessment conclusion of PFOS as *Likely to Be Carcinogenic to Humans* (USEPA, 2024c). A single epidemiological study reporting null results does not detract from

animal toxicological evidence of increased incidence of tumors due to contaminant exposure, regardless of whether the studies report on the same tumor site. The EPA relies on three evidence streams (i.e., epidemiological, animal toxicological, and mechanistic studies) to conduct hazard identification and support cancer classifications. The EPA also considers evidence across all tumor types when determining cancer classifications (USEPA, 2005). For liver cancer in particular, the EPA has provided additional discussion of all epidemiological studies reporting on incidences of liver carcinogenicity in the final toxicity assessment for PFOS (USEPA, 2024c).

The EPA classified PFOS as *Likely to Be Carcinogenic to Humans* based on evidence of carcinogenicity from animal studies and consistent mechanistic evidence of multiple potential MOAs for the tumors observed in animal studies, along with plausible but limited epidemiological evidence (USEPA, 2023a; USEPA, 2024c, Sec. 3.5.5). Although site concordance between human and animal studies is not always expected given biological differences between species (USEPA, 2005), the commenter correctly noted the importance of looking across studies reporting similar cancer types in humans and animal models. Two general population studies published since the 2016 HESDs and postdating the draft *Proposed MCLG* document (USEPA, 2023a) provide evidence of an association between PFOS and liver cancer in humans (Cao et al., 2022; Goodrich et al., 2022). A *medium* confidence nested case-control study of participants in the Multiethnic Cohort (MEC) Study in the United States observed significantly increased odds of non-viral HCC when comparing those above the 85th percentile of PFOS exposure to those below (OR = 4.50, 95% CI: 1.20, 16.00) (Goodrich et al., 2022). Results were similar in continuous analyses of PFOS exposure. A *low* confidence general population case-control study conducted in China observed significantly elevated odds of liver cancer incidence with increasing PFOS exposure (OR = 2.609, 95% CI: 1.179, 4.029, p-value for trend = 0.001) (Cao et al., 2022). Of the two studies reporting on liver cancer identified in the 2016 HESD (USEPA, 2016b), one study reported positive, non-significant evidence of an increased risk of liver cancer (Alexander et al., 2003). As noted by Alexander et al. (2003), some imprecision is expected due to a lack of individual exposure level measures or analyses (which could introduce exposure misclassification) and a lack of adjustment for potential confounders, such as smoking, both of which are common for standardized mortality ratio studies. The findings in a Danish population-based study (Eriksen et al., 2009) did not provide evidence of an increased risk of liver cancer and were generally imprecise, likely due to the small number of exposed cases. Another important difference between Eriksen et al. (2009) and Goodrich et al. (2022) is the specificity of the analysis for histological subtype. Eriksen et al. (2009) reported on all liver cancers, however, during the study's follow-up period, the incidence of HCC did not make up a large portion of liver cancers in the Danish population (Jepsen et al., 2017). More recently, the incidence of HCC has dramatically increased in the Danish population, and a follow-up study may be warranted (Jepsen et al., 2017). In response to this comment, discussion of these studies, including Eriksen et al. (2009), has been updated in the final toxicity assessment for PFOS (Section 3.5, USEPA, 2024c). Overall, the epidemiologic studies evaluating the association between PFOS exposure and liver cancer, provide sufficient evidence of an increased risk with increasing exposure (3/4). These findings further support the EPA's conclusion that

PFOS is *Likely to Be Carcinogenic to Humans* and provides tumor site concordance between the animal toxicological and human studies.

3M Company (Doc. #1774, SBC-053190)

2. Animal Evidence

EPA made similar process errors in determining that PFOS is "likely to be carcinogenic to humans" based on the results of neoplastic tumor data for the liver and pancreatic islet cells from a 2-year chronic dietary study (cited as Thomford, 2002 and Butenhoff et al. 2012, for the original study report and published peer-reviewed manuscript, respectively). While the original study data (by Thomford 2002) reported statistically significant increases in liver adenoma incidences in both male and female rats at the highest dose, it did not conclude such for the pancreatic islet cell tumors.

With regards to the hepatocellular tumor data observed in rats, EPA did not take the known biological plausibility into consideration as it related to human health and used two different models to interpret animal studies regarding PFOS carcinogenicity, which violates its own Guidelines for Carcinogenic Risk Assessment. In the draft PFOS appendix (USEPA 2023d), EPA states about data on hepatocellular adenomas and carcinomas in female rats, "the best fitting model was the Multistage Degree 1 model based on adequate p-values" (p. E-55 and p. E-58). It based its selection of a BMDL10 [FN67: BMDL10 is the benchmark dose level corresponding to the 95% lower confidence limit of a 10% change.] on this model. For data for hepatocellular adenomas in male rats, EPA stated "the best fitting model was the Multistage Degree 4 model based on adequate p-values" (p.E-47). EPA fails to explain the use of different models for studies involving male and female rats in evaluating the evidence of carcinogenicity. In doing so, EPA violates its 2005 Guidelines for Carcinogen Risk Assessment, which states, "goodness-of-fit to the experimental observations is not by itself an effective means of discriminating among models that adequately fit the data."

EPA deemed the study by Butenhoff et al (2012) a "high confidence study" (USEPA 2023c, p. 3-260), which should add to the importance of its correct interpretation and the representation of the study's result. However, EPA over-interpreted the importance of a "statistically significant trend of increased incidence of pancreatic islet cell carcinomas with increased PFOS dose" in male rats in the cancer classification section (USEPA 2023c, p. 3-296). It is important to understand that a trend, even if it is statistically significant, simply indicates a non-zero slope among data points. A trend is non-quantitative and does not imply that the magnitude of the increase in effect over increasing dose ever reaches biological significance, or that it would result in the observation of statistically significant increase in effects. A trend simply means that there is a consistent change within the observed parameters across the doses that were investigated. This does not necessarily mean that it continues to persist when additional experimental data is introduced, or that it ever reaches statistical or biological significance before reaching a

physiological maximum dose limit such as stomach capacity for dosing, or the natural lifetime of rats.

With regards to the pancreatic islet cells tumors, the EPA improperly employed an alternative statistical approach which led to a statistical significance in trend for the pancreatic islet cell carcinoma. Specifically, the original study report by Thomford (2002) calculated the total tumor incidence rate based on the total number of the tissues examined per specific dose group upon study termination at the end of two years. Given that age-related mortality is quite common among rodents in long-term studies, it is worth noting that the original statistical trend analysis (reported in Thomford 2002) did adjust for survival and survival was taken into account for the logistic regression of tumor prevalence and binary regression analyses. The EPA, on the other hand, calculated the tumor incidence rate based on the number of animals alive at the time when the tumor first occurred, which was an attempt to adjust for survival as well as excluding a subset of rats from control (n=10) and the highest dose group (n=10) that were sacrificed at week 52. While the EPA does not have any specific publication on how to analyze tumor incidence data, the guidance document from U.S. FDA Center for Drug Evaluation and Research (Lin 2007) summarizes various ways of analyzing tumor data in rodents by adjusting for intercurrent mortality, it did not, however, mention this particular approach taken by the EPA.

It was also not best practice to exclude subsets of rats from control (n=10) and the highest dose group (n=10) that were sacrificed at week 52 from the overall trend analysis for tumors, given that the trend test was adjusted for survival. All the animals in these two subgroups were subject to the same rigor in terms of specimen collections and pathology evaluations for potential presence or progression of tumor formations, if any. This was the ultimate purpose of the 2-year cancer study hence if anything, the interim evaluations (with proper survival time adjustment) did not "dilute", but rather, reflect additional statistical power to ascertain the likeliness of tumor outcome. Furthermore, in accordance with the guidance from the American Statistical Association (Wasserstein and Lazar 2016), a hard cut-off for statistical significance on its own should not be used to make scientific conclusions – "Scientific conclusions and business or policy decisions should not be based only on whether a p-value passes a specific threshold." Therefore, the interpretation should not be based on whether a p-value is above or below 0.05. On that note, the relationship between pancreatic islet cell carcinoma and PFOS treatment is further called into question because there was no increased incidence of pancreatic islet cell hyperplasia (Thomford 2002). This is important because an increase in islet cell hyperplasia is typically viewed as a continuum to develop islet cell neoplasm.

Lastly, best practice required consideration that it has been well-documented that there are substantial differences in pancreatic islet cells between rodents and humans in terms of anatomy, cellular components, gene expressions, and functional aspect of insulin secretion (Brissova et al. 2015; Steiner et al. 2010). For instance, human islet cells contain less β-cells and more α-cells relative to rodents; and the pancreas tissue in rats are highly vascular. The species difference in pancreatic islet architecture and composition begs the question regarding the interpretation and extrapolation of rodent data finding to humans.

EPA Response: As discussed throughout the administrative record and consistent with the SDWA, the EPA disagrees that there were process issues related to the development of the toxicity assessments for PFOA and PFOS; the EPA has identified and used the best available, peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices and data collected by accepted methods or best available methods and considered internal review and external peer-review input in reaching conclusions (see sections 4.1.2 and 4.1.3 of the EPA response in this *Response to Comments* document).

The commenter stated that the EPA failed to explain its use and selection of different models to quantify the observed hepatocellular tumors in male and female rats, which the commenter stated was inconsistent with the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005). The EPA disagrees. First, the quantification of the observed dose-dependent increase in hepatocellular tumors in males and female rats is inconsequential to the cancer classification applied to PFOS. The EPA concluded that PFOS is L*ikely to Be Carcinogenic to Humans* because of the observed multi-sex and multi-site tumorigenesis in response to PFOS exposure, including hepatocellular tumors (Thomford, 2002; Butenhoff et al. 2012a) in line with the 2005 Cancer Guidelines (USEPA, 2005). Regardless, the EPA disagrees that the agency did not provide further explanation aside from model fit as to why specific model outputs were selected; the EPA explained the selection of models in quantifying the hepatocellular tumors in male and female rats. For male hepatic adenomas, the EPA stated on page E-48 of the draft toxicity assessment for PFOS that all multistage models had "adequate fit (p-values greater than 0.1), [and] the BMDLs were sufficiently close (less than threefold difference)," however, "the Multistage Degree 4 model had the lowest AIC" (USEPA, 2023c). Similarly, for the hepatocellular adenomas and carcinomas in females, the EPA stated on page E-58 that all multistage models had "adequate fit (p-values greater than 0.1), [and] the BMDLs were sufficiently close (less than threefold difference)," however, "the Multistage Degree 1 model had the lowest AIC" (USEPA, 2023c). Therefore, the EPA did not rely solely on the p-values for model selection as the commenter suggests but did follow the recommendations provided in the EPA's *Benchmark Dose Technical Guidance* when considering and selecting models to derive PODs (Section 2.3.2, USEPA, 2012). In response to this comment, the EPA updated the language describing model selection in Appendix E and Section 4.2 of the final toxicity assessment for PFOS to ensure clarity (USEPA, 2024c; USEPA, 2024b). The EPA followed the standard, recommended approach "to prefer the multistage model for cancer dose-response modeling of cancer bioassay data (Gehlhaus et al., 2011). The multistage model (in fact a family of different stage polynomial models) is sufficiently flexible for most cancer bioassay data, and its use provides consistency across cancer dose-response analyses" (USEPA, 2012).

The commenter also mistakenly claimed that the EPA did not consider biological plausibility of hepatocellular tumors in rats when, in fact, the EPA did consider this factor in an extensive analysis of the MOA for hepatocellular tumors in rats (Section 3.5.4.2 of the draft toxicity assessment published for public comment; USEPA, (2023a)), as well as the final PFOS toxicity assessment (USEPA 2024b). In this section, the EPA addressed the question of human relevance of hepatocellular tumors in rats and concludes that "there is an absence of definitive information

supporting a single, scientifically justified MOA; in fact, there is evidence supporting the potential for multiple plausible MOAs." More specifically, the EPA determined that the MOA for hepatocellular tumors in rats was not entirely dependent on peroxisome proliferator-α activity, a MOA that this commenters and others claim may not be relevant to humans (Klaunig et al., 2003; Corton et al., 2014; Corton et al., 2018). The EPA identified several other potential modes of action for liver tumors that have human relevance (e.g., a cytotoxicity MOA) and may also play a role in the hepatic tumors resulting from PFOS exposure observed in rats. However, the EPA does not have adequate data to make a definitive conclusion about the mode(s) of action operative for PFOS-induced liver tumors, though a definitive conclusion about the MOA(s) underlying a particular tumor type are not required for determination of human relevance or to support the cancer classification for a contaminant. According to the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005), "[i]n the absence of sufficiently, scientifically justifiable mode of action information, EPA generally takes public health-protective, default positions regarding the interpretation of toxicologic and epidemiologic data; animal tumor findings are judged to be relevant to humans." This conclusion has since been strengthened by the publication of two epidemiological studies that show positive associations between PFOS and HCC in humans (Cao et al., 2022; Goodrich et al., 2022). Results of both studies are provided above in the EPA response to comment Doc. #1774, SBC-053187 in section 4.1.4.2 in this *Response to Comments* document. The EPA also describes the implications of these studies in section 3.5.1 of the final toxicity assessment for PFOS (USEPA, 2024c).

The commenter correctly stated that Thomford (2002) did not make conclusions about the pancreatic islet cell carcinomas observed in male rats. The commenter incorrectly argued that because the Butenhoff et al. (2012a) study was rated *high* confidence, the EPA should assume that the study authors correctly interpreted the pancreatic islet cell tumor data. Importantly, conclusions about the study confidence rating for the Butenhoff et al. (2012a) study are irrelevant to discussions on pancreatic islet cell tumors because the Butenhoff et al. (2012a) study does not include the pancreatic tumor data from the Thomford (2002) report. Therefore, the EPA cannot rely on the study author's conclusions regarding pancreatic islet cell tumors. Moreover, as part of the systematic review process, the EPA critically evaluates the available data through study quality evaluations and data extraction of individual studies as part of the systematic review process. Study quality evaluations are independent from the direction or magnitude of study findings (USEPA, 2022a). During the data extraction step, the EPA may extract the context surrounding study findings (e.g., the author's conclusions regarding an endpoint), although the study optimally provides quantitative dose-response data that can facilitate development of toxicity values (i.e., RfDs and CSFs), which the EPA extracts regardless of magnitude or direction of effect or of the author's conclusions about said data (USEPA, 2022a). The EPA analyzes the information provided in peer-reviewed studies as well as unpublished studies which contain data collected by accepted methods or best available methods (in this case, studies submitted under TSCA Section 4 (chemical testing results); Section 8(d) (health and safety studies); Section 8I (substantial risk of injury to health or the environment notices); and For Your Information (FYI) submissions consistent with USEPA,

2022a) to make data-driven, independent weight of evidence determinations regarding the conclusions of individual studies as well as conclusions about the entirety of evidence for an endpoint or health outcome.

The commenter described several other criticisms of the EPA's qualitative and quantitative analysis of the pancreatic islet cell carcinoma however, the commenter did not provide substantive scientific justification for why the EPA's approach should be adjusted according to the commenter's recommendations. The commenter first noted that "the original study report by Thomford (2002) calculated the total tumor incidence rate based on the total number of the tissues examined per specific dose group upon study termination at the end of two years." However, the commenter did not specify where in the Thomford (2002) report the data can be found. The EPA identified Table 38 or Text Table 5, as potentially having the information the commenter referred to, with limitations. In Table 38, Thomford (2002) provides incidence data for only the animals that survived to terminal sacrifice (week 104). If the EPA had used this data, it would have excluded several animals that presented with evidence of islet cell carcinoma formation upon necropsy at the time of premature death (i.e., prior to week 104). The inclusion of animals that die prior to the last day of chronic treatment in statistical analyses is standard practice at the EPA (e.g., USEPA, 2011; Jinot et al., 2017) and across health agencies, including the NTP (e.g., NTP (2020)) and California Environmental Protection Agency (e.g., CalEPA, 2021) and is an accepted and agreed-upon practice in the field (Haseman et al., 1984; Gart et al., 1979; Hoel and Walburg, 1972). In fact, Butenhoff et al. (2012a) reported a subset of data from the Thomford (2002) report, including the observed hepatocellular tumors, which included animals that died prematurely in the statistical analyses of other neoplastic lesions.

In Text Table 5, Thomford (2002) provides all reported incidences of pancreatic islet cell carcinomas in rats intended for the terminal necropsy (104 weeks; n = 50 per dose group) and the 53-week interim necropsy (n = 10 for control and high dose groups only). The number of animals presenting with tumors in each dose group reported in this table are the same as the number of animals the EPA used in its quantification of carcinogenic effects (i.e., PFOS CSF derivation; 1, 2, 2, 5, and 5 animals with pancreatic islet cell tumors in the 0, 0.5, 2, 5, and 20 ppm dose groups, respectively). However, in this table, Thomford (2002) combined the total number of animals examined across both the terminal and interim sacrifice time points. This led to an addition of 10 animals, none of which presented with pancreatic islet cell tumors, in the control (0 ppm) and high dose (20 ppm) groups. The EPA determined this approach to be biologically and statistically inappropriate. From a biological perspective, this approach was inappropriate because the prevalence and severity of lesions, particularly neoplastic lesions, is expected to be very different in animals that were administered PFOS for only half the exposure duration (i.e., 53 weeks) compared to the animals assigned to terminal sacrifice (i.e., 104 weeks). As stated in the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005), "[b]ecause of the often long latency period in cancer development, the likelihood of observing an effect also depends on whether adequate time has elapsed since exposure began for effects to occur." Indeed, there is no evidence to support that rats treated with PFOS according to the study design used by Thomford (2002) would present with pancreatic carcinomas after only 53 weeks of

exposure; the first reported incidence of pancreatic islet cell carcinoma in male rats was day 542 (approximately 77 weeks). From a statistical perspective, this approach is inappropriate because, in contrast to the commenter's claims that combining these groups "reflect[s] additional statistical power to ascertain the likeliness of tumor outcome," it decreases the percent of animals with tumors in the high dose group by adding animals that were highly unlikely to present with neoplastic lesions to the total number of animals examined, effectively biasing this response towards the null. While increasing the sample size of animals *treated in the same way* (i.e., administered PFOS for 104 weeks) would increase the statistical power of the response, combining groups that were treated very differently (e.g., when some animals were administered PFOS for half the exposure duration of another group) does not. This is supported by the observed decrease in the p-value associated with the trend test for this response reported by Thomford (2002): including the 10 interim animals in the control and high dose groups results in a p-value of $p = 0.0681$ while the p-value resulting from the EPA's independent analysis excluding the 10 interim animals in the control and high dose groups is $p = 0.0390$. Additionally, draft guidance from the Food and Drug Administration (FDA) states that in a situation when there are no observed tumors in animals from earlier time intervals, "the data for these intervals will not contribute anything to the test statistic, and these intervals may be ignored" (FDA, 2001). These biological and statistical implications are also the basis of the EPA's rationale for excluding rats that experienced premature mortality at a time prior to the first recorded occurrence of pancreatic islet cell tumors from statistical analyses and CSF derivation. As the EPA noted in both the draft and final PFOS toxicity assessments, "[e]xpressing incidence in this way quantitatively eliminates animals that died prior to the PFOS treatment duration plausibly required to result in tumor formation in the critical study" (USEPA, 2023a; USEPA 2024b). The EPA also notes that this is the same approach used for the cancer assessment of PFOS conducted by CalEPA (CalEPA, 2021) and has been used previously by the EPA (e.g., Jinot et al., 2017).

The commenter lastly questioned the significance of these tumors providing citations related to pancreatic hyperplasia and species-specific differences in pancreatic function. First, the commenter stated: "…there was no increased incidence of pancreatic islet cell hyperplasia (Thomford 2002). This is important because an increase in islet cell hyperplasia is typically viewed as a continuum to develop islet cell neoplasm." However, the commenter did not provide a citation supporting the claim that hyperplasia is a "continuum to develop pancreatic islet cell neoplasm" or that the observance of increased hyperplasia is necessary to consider the observed islet cell neoplasms significant. Second, the commenter stated that there are differences in pancreatic islet cells between rodents and humans and that these differences "begs the question regarding the interpretation and extrapolation of rodent data finding to humans." To address this issue, the EPA conducted a MOA analysis to identify information that may explain key events in the development of pancreatic islet cell tumors resulting from PFOS exposure. This discussion is available in Section 3.5.4.3 of the final toxicity assessment for PFOS (USEPA, 2024c). After review of the few available studies exploring the relationship between PFOS exposure and pancreatic tumors, the EPA determined there are currently no established modes of action for pancreatic islet cell carcinogenicity in humans or animals exposed to PFOS. As noted in a recent

review of the molecular mechanisms of pancreatic islet cell (i.e., neuroendocrine) tumors, "[a]lthough [pancreatic neuroendocrine tumors] originate primarily from aberrantly proliferating cells of the endocrine pancreas, they can also develop from pluripotent cells of the exocrine pancreas" (Maharjan et al., 2021). Some studies suggest a role for PPARα and PPARγ in rat and human pancreatic islet cell function (Sugden et al., 2001; Dubois et al., 2000; Roduit et al., 2000; Eibl et al. 2001), though PPARα activation has been argued to be related specifically to pancreatic acinar cell tumors rather than to islet cell tumors (e.g., Klaunig et al., 2003). Other studies have shown that PFOS exposure can lead to reduced pancreatic islet cell size and viability and can induce reactive oxygen species (ROS) (Qin et al., 2022). Considerable uncertainty remains in the underlying mechanisms of PFOS-induced pancreatic islet tumors. According to the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005), ""[i]n the absence of sufficiently, scientifically justifiable mode of action information… animal tumor findings are judged to be relevant to humans."

Additionally, Steiner et al. (2010), cited by the commenter, states that structural differences between the pancreas of various species may reflect "adaptation induced by altered physiological conditions, rather than inherent disparities between species." The authors provided an example of this in rodents, "the islets from diabetic *db/db* leptin receptor mutant mice display a random internal organization with a higher ratio of α-cells similar to that seen in humans," illustrating how physiological or genetic conditions may alter pancreatic cellular organization. Due to potential interindividual variability in human pancreatic structure, there remains significant debate over similarities with the rodent pancreas. Bonner-Weir et al. (2015) described this further and concluded "the human islet is similar to the rodent islet," regarding β-cell numbers, islet cell patterns, and blood vessel-islet structure and interactions, issues that were raised by the commenter.

Finally, the EPA's guidelines state that "site concordance is not always assumed between animals and humans," meaning that the occurrence of pancreatic tumors in rats may not necessarily translate directly to the occurrence of pancreatic tumors in humans (USEPA, 2005). The observation of pancreatic tumors in rodents reflects on the carcinogenic potential of PFOS in general, and not necessarily a particular tumor type expected to occur in humans.

3M Company (Doc. #1774, SBC-053196)

3. Mechanistic Evidence

EPA's processes also undermine its conclusion that PFOS is likely to be carcinogenic to humans based on mechanistic evidence. Mechanistic evidence is critical to support the relevance of data to carcinogenicity, with specific focus on relevance to carcinogenicity in humans. Mechanistic information is relevant to assess the applicability of findings in animals to human cancer risk. EPA (USEPA 2005) specifically emphasizes the importance of making "decisions about potential modes of action and the relevance of animal tumor findings to humans." As discussed below, profound uncertainties compromise the agency's following statement about hepatic tumors in

animals: “the available studies provide varying levels of support for the role of several plausible MoAs: PPARα activation, chimeric antigen receptor (CAR) activation, hepatocyte nuclear factor 4 alpha (HNF4α) suppression, cytotoxicity, genotoxicity, oxidative stress, and immunosuppression.” (USEPA 2023c, p.3-284). Each of these modes of action is discussed below.

PPARα Activation. EPA’s treatment of PPARα as a viable theory for carcinogenicity applicable to humans directly contradicts its own scientists’ conclusions. EPA scientists previously published a peer-reviewed article with the title “The PPARα-dependent rodent liver tumor response is not relevant to humans” (Corton 2018) (emphasis added), which EPA cites in the proposed NPDWR. The agency failed to acknowledge its own scientists’ key finding that “[t]he PPARα-dependent rodent liver tumor response is not relevant to humans.” EPA’s insistence on the relevance of this pathway with respect to PFOA and PFOS is further drawn into question by findings from EPA scientists who demonstrated last year (Evans et al. 2022) that the endogenous fatty acid oleic acid, which is also ubiquitous in the diet, is a more potent PPARα activator than are PFOA (by more than 1 order of magnitude) and PFOS (by more than 2 orders of magnitude). If PPARα activation were a relevant pathway to human liver tumors, that disease state presumably would be at epidemic levels, based on oleic acid alone.

In addition, EPA (Evans et al. 2022) reported concentrations of PFOS and PFOA that did not induce PPARα activity, which demonstrates that this alleged key MOA for carcinogenicity is, if anything, a proven threshold effect. Best practice would be to apply those insights to the carcinogenicity assessment of PFOS and PFOA and abandon the principle of a linear non-threshold dose response.

CAR Activation. In 2016, EPA referenced Hall et al.’s (2012) conclusion that, “CAR activation can lead to hepatocyte proliferation and hepatocarcinogenesis in animals. The human CAR receptor is relatively resistant to mitogenic effects and less likely to induce cancers through this mechanism.” EPA referenced the same publication elsewhere in the 2023 draft proposal for PFOS but neglected to report the same conclusion regarding the implausibility of CAR as MoA for PFOS carcinogenicity. EPA vaguely alluded to Hall’s conclusion on CAR in the PFOA draft proposal but failed to acknowledge its fundamental implications for human cancer risk.

Every event that is elicited by receptor binding is a threshold effect. A zero-effect threshold is inevitable at concentrations where insufficient numbers of activating molecules are present to trigger a biological signaling cascade and, thus, a response. Receptor-mediated theories warrant dismissal if proven inapplicable for human risk assessment; otherwise, they should be considered threshold effects. EPA did neither.

HNF4a Suppression. Beggs (2016) reported that concentrations of 10,000 nanomolar (nM) PFOA and PFOS had statistically significant impacts on HNF4α expression in primary human hepatocytes—and lower concentrations (i.e., 10, 100, 500, 1,000 nM) did not. This observation demonstrates the existence of a threshold below which no effect was observed. Best practice is to discontinue the use of a non-threshold approach for both PFOS and PFOA and instead use PBPK

modeling based on concentrations in drinking water to compare in vitro no-effect concentrations to expected concentration within human hepatocytes.

Cytotoxicity. In the draft document for PFOS (USEPA 2023c, p. 3-292), EPA states, "the available data indicate a parallel dose response for cytotoxicity and the formation of liver tumors as evidence in Table 3-24 and Table 3-25." It is unclear how EPA reached this conclusion from data that only show statistical significance for hepatocellular adenomas and combined hepatocellular adenomas and carcinomas, and for none of the other (cytotoxicity) endpoints. Variations on a cellular level cannot cause statistically significant tumor formation at a dose where those cellular changes are not also statistically significantly increased. A molecular event cannot be responsible for a pathological response if the dose-response curves are parallel and not intersecting. For PFOA, EPA presents evidence of cytotoxicity in vivo (i.e., "significantly increased single cell (hepatocyte) death and in necrosis in male and female was reported in Sprague-Dawley rats, with a significant dose-response trend"), but fails to conduct a dose-response assessment. Only effect concentrations of in vitro assays are mentioned in the draft document, none of which are lower than 10 µM. EPA lists non-cytotoxic concentrations but fails to use them as demonstrable no-effect levels to justify a threshold assessment of carcinogenicity.

The assessment of cytotoxicity lacks the diligence that is warranted if it is considered a key event in carcinogenesis. [FN68: It is inappropriate for EPA to set a MCLG at zero based on carcinogenicity when a substance does not have a linear mode of carcinogenic action. Chemistry Council v. EPA, 206 F.3d 1285, 1287 (D.C. Cir. 2000). When a substance exhibits a "cytotoxic" mode of action, no carcinogenic effects at low doses, a zero MCLG based on carcinogenicity is not in line with the goals of the SDWA. While there is uncertainty in the range at which no known or anticipated adverse effects on the health of persons occur, this does not mean that EPA can simply default to zero. Uncertainty allows EPA to choose the lowest MCLG within the window of uncertainty but it does not justify choosing an MCLG outside of the range of uncertainty. Id. At 1290.]

Genotoxicity. EPA concluded based on the available in vivo mutagenicity study (Wang et al. 2015) that "the evidence for mutagenicity of PFOS in vivo is negative" (USEPA 2023c, p. 3-269). Addressing DNA damage, the agency stated, "it is important to note that rat models could be ineffective for determining micronucleus formation if study authors do not use appropriate methodologies because the spleen will remove micronucleated cells" (USEPA 2023c, p.3-269). This draws the biological relevance of other models and findings into question because an effective removal of micronucleated cells implies the neutralization of this hazard. EPA should explain why said findings in other models are applicable for assessing potential human carcinogenicity.

Immunosuppression. EPA (USEPA 2023c, p.3-295) states that "the only available study in Sprague-Dawley rats […] does not indicate that immunosuppressive effects are occurring at or below doses that result in tumorigenesis." This finding demonstrates that there is no toxicological evidence that immunosuppression is a plausible MoA on the organism level because a mechanism that supposedly underlies a carcinogenic effect should occur at the same

doses that cause tumors. EPA ignores the fundamental logic that a response (e.g., cancer) that occurs at doses below the no-observable-effect-level (NOEL) of another response (e.g., immunosuppressive effects) cannot be linked to or caused by the latter. By insisting that both are linked, EPA violates the basic principle of dose-response. According to EPA's Vocabulary Catalog for Drinking Water Technical & Legal Terms (see https://sor.epa.gov/sor_internet/registry/termreg/searchandretrieve/glossariesandkeywordlists/search.do?details=&vocabName=Drink%20Water%20Tech%2Flegal%202009), the NOEL is defined as a "dose level at which no effects are noted" and dose response is defined as "the quantitative relationship between the amount of exposure to a substance and the extent of toxic injury produced". If the extent of toxic injury from immunosuppression is zero, then it cannot be in a quantitative relationship with cancer that allegedly occurs below the NOEL of immunosuppression.

The perpetual inconsistency of EPA's findings and interpretations warrants a detailed analysis to compare and contrast reported dose-responses and clinical relevance of experimental models.

4. Structural Similarities EPA inappropriately attempts to rely on the structural similarity between PFOA and PFOS to conclude that its carcinogenicity determination PFOA applies to PFOS. EPA's reasoning of structural similarity for cancer risk read-across (USEPA 2023c, p. 3-296) between PFOA and PFOS is also not supported by evidence. EPA states in its publication by Patlewicz et al. (2019) that "the Environmental Protection Agency had the greatest experience in using readacross" but failed to apply any of the best practices – or even apply its own Generalized ReadAcross Tool (https://www.epa.gov/chemical-research/generalized-read-acrossgenra#:~:text=Chemical%20read%2Dacross%20is%20a,(e.g.%2C%20structural%20similarity). EPA also did not follow the seven key steps in the workflow: 1. Decision context 2. Data gap analysis 3. Overarching similarity rationale 4. Analog identification 5. Analog evaluation 6. Data gap filling 7. Uncertainty assessment. The two PFAS substances differ in a key functional group, in that PFOA is a perfluoroalkyl carboxylic acid and PFOS is a perfluoroalkyl sulfonic acid. Carboxylic acids and sulfonic acids possess different physical-chemical properties, which not only explains their different technical applications but also suggests differences in disposition and dynamics on biological receptor sites. The agency stated that a "similar set of non-cancer effects have been observed after exposure to either PFOA or PFOS in humans and animal toxicological studies," implying that those effects were of relevance for cancer risk assessment, when in fact, only the consideration of key events that actually lead to cancer is of relevance. By definition, non-cancer events are not applicable for cancer risk assessment.

EPA Response: As discussed throughout the administrative record and consistent with the SDWA, the EPA disagrees that there were process issues related to the development of the toxicity assessments for PFOA and PFOS; the EPA has identified and used the best available, peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices and data collected by accepted methods or best available methods and considered internal review and external peer-review input in reaching conclusions (see sections 4.1.2 and 4.1.3 of the EPA response in this *Response to Comments* document). Please also refer

to the EPA response to comment Doc. #1774, SBC-053190 in section 4.1.4.2 in this *Response to Comments* document for initial discussion on the human relevance of tumors reported in animal toxicological studies.

The commenter repeatedly made claims about "best practices" or recommended approaches that they did not substantiate with citations. Additionally, the commenter repeatedly stated that the EPA should use a non-linear (i.e., threshold) approach for both PFOA and PFOS, a recommendation which is inconsistent with the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005). The EPA concludes that the MOA for PFOS induced liver tumors cannot be determined based on the available evidence. Therefore, in accordance with agency guidance, "[n]onlinear approaches generally should not be used in cases where the mode of action has not been ascertained" (USEPA, 2005). As described further below, the commenter made numerous erroneous claims regarding the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) and the EPA's analyses of the mechanistic literature underlying the carcinogenicity of PFOS and PFOA.

The commenter is incorrect in its interpretation of the EPA's conclusions on the relevance of PPARα-induced liver tumors. The EPA toxicity assessments do not include statements that PPAR-alpha induced hepatic tumors are relevant to humans. In fact, the EPA states, "some have argued that the MOA for liver tumor induction by PPARα activators in rodents has limited-to-no relevance to humans, due to differences in cellular expression patterns of PPARα and related proteins (e.g., cofactors and chromatin remodelers), as well as differences in binding site affinity and availability (Corton, 2018; Klaunig, 2003)." However, the assessment also discusses several studies which report activation of PPARα in human cell lines (see section 3.4.1.3; USEPA, 2024c). The commenter incorrectly stated that the EPA did not consider the discussion by Corton et al. (2018) in its evaluation of MOAs for liver tumors in rats. Rather, in Section 3.5.4.2.4 (Mode of Action for Hepatic Tumors) of the draft and final toxicity assessment for PFOS (USEPA, 2023a; USEPA, 2024c), the EPA cites Corton et al. (2018) several times when discussing the key events associated with PPARα-induced hepatic tumorigenesis. The EPA explicitly states: "Therefore, for PPARα activators that act solely or primarily through PPARα-dependent mechanisms (e.g., Wyeth-14,643, di-2-ethyl hexyl phthalate), the hepatic tumorigenesis observed in rodents may be expected to be reduced in frequency or severity or not observed in humans (Klaunig, 2003; Corton, 2014; Corton, 2018)." However, evidence exists that the liver tumorigenic responses to PFOS and PFOA are likely not entirely PPARα-dependent. Prior to the release of the public comment draft toxicity assessments published at the time of rule proposal, the EPA reviewed data related to other mechanisms of carcinogenesis in the liver and identified information related to key events in the development of hepatic tumors resulting from PFOS and PFOA exposures (Section 3.5.4.2, USEPA, 2023f; USEPA, 2023a). Evidence for MOAs for hepatic tumors other than PPARα activation, namely constitutive androstane receptor (CAR) activation and cytotoxicity, were reviewed in addition to the evidence for the PPARα activation MOA. The data related to these additional MOAs not only generally provide further mechanistic evidence supporting the potential for multiple MOAs underlying

PFOS and PFOA hepatic carcinogenicity, but also provide evidence that hepatic tumors caused by these contaminants may be relevant to humans.

The commenter also noted that there are concentrations of PFOS or PFOA that do not induce PPARα activity and argues that this demonstrates a threshold effect. The EPA disagrees with this claim because, as shown in Section 3.5.4.2 of the PFOA toxicity assessment (USEPA, 2023f; USEPA, 2024d), male rodents demonstrated PPARα activation at every dose evaluated ranging from 1.1 to 23 mg/kg/day, with the exception of 20 mg/kg/day. Section in the PFOS toxicity assessment (USEPA, 2023a; USEPA, 2024c) similarly shows that doses of PFOS of 0.312 mg/kg/day and greater led to PPARα activation in male and female rodents. While doses lower than 0.312 mg/kg/day of PFOS did not result in PPARα activation (or subsequent hepatic tumors), all data related to doses <0.312 mg/kg/day are from a single study (Butenhoff et al., 2012a; Thomford, 2002). Nonetheless, as stated above, without a definitive MOA for PFOA- or PFOS-induced hepatic tumors, "[n]onlinear approaches generally should not be used" (USEPA, 2005). Thus, the lack of PPARα activation at some doses in a single study does not alone support a threshold effect, considering the fact that PPARα activation is not the definitive MOA for PFOS-induced hepatic tumors.

The commenter cited Evans et al. (2022), a study that measured PPARα activation in *in vitro* human and rat ligand binding domain assays, to support their position that the PPARα MOA is not relevant to humans. It should be noted that Evans et al. (2022) stated in their abstract, "*In vitro* measures of human and rat PPARα and PPARγ activity did not correlate with oral doses or serum concentrations of PFAS that induced increases in male rat liver weight from the National Toxicology Program 28-d toxicity studies," and the authors later stated, "The *in vitro* endpoints measured here were poor predictors of *in vivo* liver weight changes in male rats from the NTP 28-day studies." Given that the *in vitro* data in Evans et al. (2022) did not correlate with *in vivo* studies, those data should not be used as evidence to establish either that PFOA or PFOS do not induce PPARα activity at lower doses or a threshold. A lack of a statistically significant response in an *in vitro* assay could be interpreted as the limits of the study's sensitivity, not that the chemical is not interacting with the receptor below that dose level. Comparisons between oleic acid and PFOA or PFOS based on the Evans et al. (2022) data should similarly be viewed with caution. The commenter illogically stated, "If PPARα activation were a relevant pathway to human liver tumors, that disease state presumably would be at epidemic levels, based on oleic acid alone." If this statement was correct, all cancers that involve nuclear receptor activation would be at epidemic levels because of endogenous ligands, which is not the case. For example, endogenous estradiol would induce widespread cancers due to estrogen receptor activation. The commenter's assertion ignored the state of the science regarding complexities of nuclear receptor signaling pathways (e.g., positive and negative feedback loops) and cancer formation. As stated in the *Guidelines for Carcinogen Risk Assessment*, "carcinogenesis involves a complex series and interplay of events" (USEPA, 2005). Additionally, "[a]lthough important information can be gained from *in vitro* test systems, a higher level of confidence is generally given to data that are derived from *in vivo* systems, particularly those results that show a site concordance with the tumor data" (USEPA, 2005). Reliance solely on *in vitro* data would result in neglecting the

impact that differences in toxicokinetic factors, bioaccumulation, and elimination rates have on *in vivo* PFAS toxicity, which is clearly pointed out by Evans et al. (2022) as a relevant confounding factor for both PFOS and PFOA.

The commenter questioned the relevance of the CAR activation-induced rodent liver tumor response to humans. Prior to rule proposal, the EPA reviewed the available data related to key events in proposed MOAs to understand the plausibility that hepatic tumors resulting from PFOA or PFOS exposure develop through MOAs including CAR activation (PFOA Section 3.5.4.2.4 (USEPA, 2024d) and PFOS Section 3.5.4.2 (USEPA, 2024c)). The key events for the CAR activation MOA and the evidence underlying them are summarized in those sections. The EPA demonstrates that for PFOS, evidence for the CAR activation key events is generally not reported *in vivo*, however, there is evidence that PFOS activates CAR in human cell lines, in contrast to the commenter's claim that CAR activation is an implausible MOA for PFOS-induced carcinogenicity in humans. Similarly, for PFOA there is evidence that CAR activation, and subsequent alterations in CAR target gene expression, occur in male rodents (USEPA, 2024d). While the CAR activation MOA for liver tumors may have less evidence than some other MOAs, the available data show it to be a plausibly human-relevant MOA.

The commenter stated, "Receptor-mediated theories warrant dismissal if proven inapplicable for human risk assessment; otherwise, they should be considered threshold effects." It is worth repeating that the *Guidelines for Carcinogen Risk Assessment* state, "Nonlinear approaches generally should not be used in cases where the mode of action has not been ascertained" (USEPA, 2005), which is the case for both PFOA and PFOS. Additionally, the commenter's unsubstantiated statement that all nuclear receptor-mediated events should be wholly considered threshold effects is not supported with a citation, and the EPA disagrees with this position. The *Guidelines for Carcinogen Risk Assessment* discuss receptor binding and activation as one biological mechanism of tumor induction, but the *Guidelines* do not assert that this mechanism results in non-linear carcinogenicity (USEPA, 2005). In fact, determining that a carcinogen acts through a threshold (i.e., non-linear) MOA is difficult because it requires studies designed so that there is not "a small risk that falls below an experiment's power of detection" (USEPA, 2005). While it is true that receptor-mediated effects are typically dose-dependent, a threshold response is not always certain because non-threshold dose-responses may also occur for receptor-mediated carcinogens (Melnick et al., 1996; Bosland 2019). For example, as shown in the PFOA toxicity assessment, no identified study measured both CAR activation and hepatic tumors in male rodents at the same dose (USEPA, 2024d). CAR activation was observed for doses of 3, 10, 19, and 23 mg/kg/day PFOA for 1, 7, and 28 days, and hepatic tumors were noted at doses both lower and higher than 3 mg/kg/day in 2-year studies. Thus, it is unclear from the animal evidence whether CAR activation at PFOA levels lower than 3 mg/kg/day contributes to hepatic carcinogenicity. While CAR activation was not directly measured for PFOS, gene expression indicative of CAR activation (Key Event #2 in the MOA) was observed at doses as low as 0.312 mg/kg/day and as high as 1 mg/kg/day, and hepatic tumors were observed at 0.984 mg/kg/day in male rats (USEPA, 2024c). In female rats, altered expression of CAR target genes was observed at 0.312 and 0.625 mg/kg/day at 28 days of exposure, while tumors were not measured at these

doses. At 1.251 mg/kg/day, the tumorigenic dose in female rats, CAR target genes were differentially expressed in a different study of pregnant females exposed during gestation. CAR activation and altered gene expression related to CAR activation (the first two molecular events in the MOA) were not evaluated in the tumorigenicity studies, nor at the same doses across studies; thus, it is not possible to conclude a threshold effect based on the available data.

The commenter made similar incorrect statements about threshold responses related to HNF4α. While the commenter is correct that the *in vitro* results from one study (Beggs et al., 2016) reported significant effects for PFOA and PFOS at 10,000 nM but did not report significant effects on HNF4α protein expression in primary human hepatocytes at concentrations of 1,000 nM or lower, these data are not the sole evidence of HNF4α suppression by PFOA and PFOS. In another *in vitro* study, gene expression microarray data demonstrated that PFOA exposure inhibited HNF4α function in primary human hepatocytes, as evidenced by changes in gene targets of HNF4α using upstream regulator analysis (Buhrke et al., 2015). These changes were statistically significant at 25 and 100 µM PFOA. An *in vitro* study in HepaRG cells exposed to 1–100 µM PFOS corroborated these findings, as downregulations in both HNF4α and its target gene CYP7A1 were observed (Behr et al., 2020). Additionally, the *in vivo* results from Beggs et al. (2016) demonstrated that hepatic HNF4α protein expression was decreased *in vivo* in mice treated with 3 mg/kg/day PFOA or 10 mg/kg/day PFOS for seven days. The results from Beggs et al. (2016) are described in Section 3.4.1.3 of the toxicity assessment (USEPA, 2024c). To increase transparency, the EPA has expanded the description of these results in the final assessments (see Section 3.5.4.2 of USEPA, 2024d; USEPA, 2024c).

The commenter asserted that, "Best practice is to discontinue the use of a non-threshold approach for both PFOS and PFOA and instead use PBPK modeling based on concentrations in drinking water to compare *in vitro* no-effect concentrations to expected concentration within human hepatocytes." The commenter does not provide any basis for this assertion and does not provide the methods by which the EPA would do this. Additionally, agency guidance does not support this practice (USEPA, 2022a; USEPA, 2014a). The EPA does not agree that a threshold approach should be taken for this single endpoint based on one (PFOS) or two (PFOA) *in vitro* studies, nor does this endpoint support the application of a threshold approach for the assessments of PFOA or PFOS carcinogenicity. The commenter again did not provide a citation substantiating their claim that best practice would be to use a modeling approach based on *in vitro* data. Furthermore, the commenter's approach is inconsistent with recommendations regarding interpretation of mechanistic data outlined in the *ORD Staff Handbook for Developing IRIS Assessments* (e.g., Section 6.2.1, USEPA, 2022a).

Further, HNF4α suppression represents only one possible mechanism that may be related to hepatotoxicity and hepatic carcinogenicity of PFOA and PFOS but does not alone represent an established MOA. The EPA has organized sections within the Section 3.5.4.2 (Mode of Action Analysis) of the toxicity assessments to highlight proposed MOAs for which data are available across multiple key events, in contrast to mechanistic evidence that does not currently "map" to a specific proposed MOA (USEPA, 2024d; USEPA, 2024c). HNF4α suppression does not alone

satisfy the criteria in the *Guidelines* that must be met for a nonlinear approach to be selected for dose-response analyses: "when there are sufficient data to ascertain the mode of action and conclude that it is not linear at low doses and the agent does not demonstrate mutagenic or other activity consistent with linearity at low doses" (USEPA, 2005).

The commenter questioned the EPA's characterization of cytotoxicity as a key event in hepatic carcinogenesis. In the proposed rule, the EPA conducted a MOA analysis to identify and organize evidence related to key events in the development of hepatic tumors resulting from PFOA or PFOS exposure (PFOA Section 3.5.4.2.4 (USEPA, 2024d) and PFOS Section 3.5.4.2 (USEPA, 2024c)). Specifically, the EPA summarized the evidence underlying the cytotoxicity MOA for hepatic tumors at several doses. As shown in the PFOA assessment, there are doses at which both cytotoxicity is significantly increased and hepatic tumors occurred in male rats (specifically at 2.2 and 4.6 mg/kg/day for PFOA and 0.984 mg/kg/day for PFOS; NTP (2020), Thomford (2002), and Butenhoff et al. (2012a), respectively). The commenter stated, "Variations on a cellular level cannot cause statistically significant tumor formation at a dose where those cellular changes are not also statistically significantly increased." The commenter did not provide support or a citation for this statement. The EPA disagrees with this unsubstantiated statement; while cellular changes measured at earlier timepoints may not reach statistical significance, this does not preclude the possibility of a cytotoxic MOA nor does it provide evidence against a cytotoxic MOA. In response to this comment, the evidence for the key events in the tables of the final assessments (USEPA, 2024d; USEPA, 2024c) now differentiate between evidence that is reported but not statistically significant (labeled as "–") and lack of data (labeled as "not reported" or "NR"). Because the term "parallel" appeared to confuse the commenter, the EPA updated the language to more clearly describe consistencies in the dose-response relationships of this MOA (USEPA, 2024d; USEPA, 2024c). The intent of the statement, "the available data indicate a parallel dose response for cytotoxicity and the formation of liver tumors," was to demonstrate that the dose-response curves for cytotoxicity and for hepatic tumorigenesis were both non-monotonically increasing with dose.

The commenter erroneously stated that the EPA did not conduct dose-response assessments of cytotoxicity endpoints. For PFOS, BMD modeling for Butenhoff et al. (2012a)/Thomford (2002) for hepatocellular adenomas is included in PFOS Appendix E for male and female rats, for combined hepatocellular adenomas and carcinomas in female rats, and for individual cell necrosis in the liver for male and female rats(USEPA, 2024c; USEPA, 2024b). For PFOA, BMD modeling for NTP (2020) is included in Appendix E.2.6 (USEPA, 2024a). The EPA modeled hepatocyte single cell death in male rats following post-weaning exposure, necrosis in the liver in male rats following postweaning exposure, hepatocellular adenomas in male rats following postweaning exposure, and hepatocellular adenoma or carcinoma in male rats following postweaning exposure. Finally, BMD modeling for the endpoints of focal necrosis and individual cell necrosis in male mice was modeled from Loveless et al. (2008).

The commenter's statements appear to call into question the biological relevance of genotoxicity findings across all model organisms and assays because of the EPA's discussion of the biological

limitations and methodological requirements associated with one assay measuring micronuclei formation in erythrocytes in the peripheral blood of rats. The EPA disagrees with the commenter's extrapolation from this assay to all genotoxicity data because this particular issue is an established limitation of the micronuclei assay in rats, as described in the reference provided in the draft toxicity assessments (Schlegel and MacGregor, 1984). For example, the cells with point mutations and deletions detected by the transgenic rodent assay reported in Wang et al. (2015) would not have been subject to splenic removal and, therefore, not subject to this limitation. The EPA also notes that there is available literature describing optimal and reliable methods for quantifying micronuclei formation in rats (Witt et al., 2000; WHO, 2020). Because the studies reporting micronuclei in rats following PFOS and PFOA exposures were conducted according to these standards, thereby avoiding the potential for false negative results, the text describing this issue has been removed from the toxicity assessments. In addition, it should be clarified that the potential hazard of genetic damage from exposure to a genotoxic agent is not "neutralized" in animals with a spleen. The identification of genotoxic agents is facilitated by assays that are simple, sensitive, and specific to detecting heritable genetic alterations. The endpoint of micronucleus formation in immature or mature erythrocytes in mammalian peripheral blood has become a standard of genotoxicity testing due to the ease of the collection and analysis of these cells and serves as a marker for genotoxic risk to all exposed tissues, provided appropriate test conditions are employed (e.g., OECD 474).

The commenter asserted that immunosuppression cannot be a plausible MOA for carcinogenicity and misleadingly cited an out of context excerpt of one sentence from the draft PFOS assessment (USEPA, 2023a) to support this assertion. The commenter neglected to acknowledge the full scope of evidence for immunosuppression already provided. The full context of that paragraph in the PFOS document states:

"Animal toxicological studies also report markers of immunosuppression, including reductions in natural killer cell activity. As described in Section 3.4.2.2, there are several reports of decreased natural killer cell activity in male and female, adult and F1 generation mice from short-term, subchronic, and gestational studies (Dong, 2009; Peden-Adams, 2008; Keil, 2008; Zhong, 2016; Zheng, 2009). While one short-term study in male mice reported increases in splenic T-helper (CD3+CD4+) and T-cytotoxic (CD3+CD8+) lymphocytes (Lv, 2015), two gestational studies reported reductions in thymic CD4+ cells in male offspring (Zhong, 2016; Keil, 2008). There is also limited evidence of immunosuppression in the form of reduced white blood cell counts (primarily lymphocytes) from two short-term rodent studies in male mice and rats, respectively (Qazi, 2009; NTP, 2019c). This short-term report is the only available study in Sprague-Dawley rats and does not indicate that immunosuppressive effects are occurring at or below doses that result in tumorigenesis (NTP, 2019c). However, it is difficult to discount immunosuppression as a potential MOA for PFOS, given the limited database for rats and stronger databases indicating immunosuppression in mice and humans."

Information presented throughout the toxicity assessments describes the immunosuppressive effects of PFOA and PFOS, including immunosuppression observed in human epidemiological

studies (USEPA, 2024d; USEPA, 2024c). The evidence profile tables for Immune Effects, show the weight of the evidence from evaluating and synthesizing multiple human and animal studies which provide evidence for immunosuppression following PFOA and PFOS exposure (Section 3.4.2; USEPA, 2024d; USEPA, 2024c). Therefore, the EPA maintains that immunosuppression represents a plausible underlying mechanism involved in PFOA- and PFOS-induced tumorigenesis.

Finally, the commenter criticized the EPA's discussion on the structural similarities between PFOA and PFOS when determining the weight of evidence for PFOS carcinogenicity. A response to this comment is provided in section 4.1.4 of the EPA response in this *Response to Comments* document.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053421)

In response to the SAB requests, EPA presents in the Public Comment Draft Assessments a finding of "likely to be carcinogenic" for both PFOA and PFOS. This is striking because EPA did so without an SAB recommendation. The SAB Report did not recommend a "likely to be carcinogenic" classification for PFOS. This new classification for PFOS relies on the same exact data that EPA used in the Draft PFOS Assessment, but EPA has reinterpreted it to raise the classification. In the December 2021 Draft PFOS Assessment, EPA recommended the "suggestive" classification, explaining that "[t]he available epidemiological and animal toxicity data suggest a potential concern for carcinogenic effects in humans but are not sufficient for a stronger conclusion."[FN125: See Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) (CASRN 1763-23-1) in Drinking Water (PFOS Draft Assessment), at page 312, available at: .epa.gov/ords/sab/f?p=100:18:16490947993:::RP,18:P18_ID:2601.] Yet, in the March 2023 Public Comment Draft Assessment, after discussing the same studies considered in 2016 HESD [FN126: U.S. EPA (2016) Health Effects Support Document for Perfluorooctanoic Acid (PFOA). (EPA 822-R-16-003). (HESD) Washington, DC, U.S. Environmental Protection Agency, Office of Water. .epa.gov/sites/default/files/2016-05/documents/pfoa_hesd_final-plain.pdf.] and in the 2021 Draft Assessment, EPA states "EPA has now determined the available data for PFOS surpass many of the descriptions for Suggestive Evidence of Carcinogenic Potential."[FN127: See Public Comment Draft Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) in in Drinking Water (Public Comment Draft Assessments), at page 6-8, available at: .regulations.gov/document/EPA-HQ-OW-2022-0114-0034.] EPA appears to reinterpret the studies by Thomford 2002 and Butenhoff 2012 without explanation [FN128: Id. At Section 6.4. In contrast, in the 2021 Draft Assessment, at page 312, EPA states: "Additionally, the animal evidence for PFOS is limited to a single chronic cancer bioassay. Although liver adenomas were significantly increased in male and female rats at the highest dose and a positive trend was observed ($p = 0.03$), a dose-response pattern was not observed. Incidence of thyroid follicular tumors and mammary gland tumors also did not show a direct response to dose."]. EPA also adds a new criterion, which is not part of the EPA 2005 Guidelines for Carcinogens, and adds that "Structural similarities between PFOS and PFOA add

to the weight of evidence for carcinogenicity of PFOS."[FN129: Id. At page 3-296.] These findings also contradict EPA's 2023 Economic Analysis, which states "Evidence of a positive association between PFOS exposure and kidney cancer was inconclusive; the small number and limited scope of studies at the time were inadequate to make definitive conclusions (U.S. EPA, 2016e; U.S. EPA, 2023d)."[FN130: See EPA Economic Analysis of the Proposed National Primary Drinking Water Regulation for Per- and Polyfluoroalkyl Substances, 2023, at page 6-16.]

EPA's 2023 reinterpretation of the same studies it reviewed in 2016 and 2021, as well as EPA's addition of new considerations (e.g., a novel consideration of similarity to other chemistries), requires external peer review. This is not a minor change. The effects of a change from "suggestive to be carcinogenic" to "likely to be carcinogenic" for PFOS are highly significant to this rulemaking. Because of this higher cancer classification, EPA is now proposing an MCLG of zero for PFOS; whereas, if EPA had retained the cancer classification from the 2016 HESD and the 2021 Draft Assessment, the MCLG would be higher. While SDWA requires that EPA request comments from the SAB prior to proposing the MCLG,[FN131: 42 U.S.C. [sec] 300g-1(e).] there is no record from the SAB to support EPA's new determination for PFOS, nor is there any SAB review of the new structured framework that EPA developed to inform the most recent cancer classification. EPA's change in the cancer classification of PFOS without additional peer review of the new framework and its application to PFOS should not be finalized.

Further, until there is additional review and endorsement of EPA's proposed cancer classification for PFOS, EPA should not quantify the cancer effects of PFOS.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document. The commenter misstates or mischaracterizes several of the EPA's conclusions and the SAB's recommendations. For example, the commenter's statements that the SAB did not recommend a *Likely to Be Carcinogenic to Humans* classification for PFOS and that the EPA did not explain its reinterpretation of studies cited in the 2016 HESD (USEPA, 2016b) or the 2021 *Proposed Approaches* (USEPA, 2021c) document leading to the agency's updated PFOS cancer classification are incorrect and are addressed in the EPA response to comment Doc. #1774, SBC-045684, SBC-053187, SBC-053190, and SBC-053196 in section 4.1.4.2 in this *Response to Comments* document. An explicit description of the EPA's rationale for updating the cancer classification for PFOS was provided in the public comment draft assessment (USEPA, 2023a) and is similarly presented in Section 5.4 of the final toxicity assessment (USEPA, 2024c).

The commenter additionally asserted that the EPA should not quantify the cancer effects of PFOS until there is endorsement of the proposed cancer classification. The EPA disagrees and in fact, the SAB did support and endorse quantification of cancer effects of PFOS (USEPA, 2022b). As described in the EPA response to comment Doc. #1774, SBC-045690 in section 13.4.1 in this *Response to Comments* document, the SAB PFAS Review Panel stated that the EPA was "overly conservative in dismissing the appearance of a dose-response relationship for [hepatocellular carcinoma], particularly in females…Given that multiple MOAs may be operative in this outcome, the Panel suggests that the EPA reevaluate the 2012 Butenhoff study" (USEPA, 2022b).

Therefore, the SAB endorsed both the EPA's reevaluation of the critical study (i.e., Butenhoff et al. (2012a)/Thomford (2002)) and the critical effect (i.e., hepatocellular tumors in female rats).

Additionally, even if the EPA had maintained the *Suggestive Evidence of Carcinogenicity* descriptor for PFOS, the EPA would have been consistent with agency guidance in quantifying a CSF according the 2005 *Guidelines for Carcinogen Risk Assessment*, which states that "when the evidence includes a well-conducted study, quantitative analyses might be useful for some purposes, for example, providing a sense of the magnitude and uncertainty of potential risks, ranking potential hazards, or setting research priorities" (USEPA, 2005). As the commenter notes, the Butenhoff et al., (2012a) is a *high* confidence study.

In addition, even if the EPA had maintained the draft *Suggestive Evidence of Carcinogenicity* descriptor for PFOS (USEPA, 2021c) and the MCLG was based on noncancer effects, calculating the MCLG based on the overall noncancer RfD for PFOS (1 x 10^{-7} mg/kg/day; USEPA, 2024c) would still result in an MCLG below the Maximum Contaminant Level (MCL) finalized in this rulemaking (4 ppt). For example, if the EPA had based the MCLG for PFOS on the critical effect of increased total cholesterol in adults, which is relevant to the population with the lowest bodyweight-adjusted drinking water consumption rate (USEPA, 2019) (i.e., the general population and not a vulnerable population such as formula-fed infants), the MCLG would be 0.6 ng/L (ppt). This example noncancer-based MCLG for PFOS is calculated as follows and summarized in the table below:

$$\mathbf{MCLG} = \left(\frac{\text{RfD}}{\text{DWI-BW}}\right) * \text{RSC}$$

$$= \left(\frac{0.0000001 \ \frac{\text{mg}}{\text{kg/day}}}{0.034 \frac{\text{L}}{\text{kg/day}}}\right) * 0.2$$

$$= 0.0000006 \ \frac{\text{mg}}{\text{L}}$$

$$= 0.6 \ \frac{\text{ng}}{\text{L}} \text{ or parts per trillion (ppt)}$$

Table 4-1. PFOS Noncancer-Based MCLG – Input Parameters and Value

Parameter	Value	Units	Source
Chronic oral RfD[a]	1E-07	mg/kg/day	RfD based on co-critical effect of increased total cholesterol in adults (Dong et al., 2019; USEPA, 2024c).
DWI-BW	0.034	L/kg/day	90th percentile 2-day average, consumer-only estimate of combined direct and indirect community water ingestion for adults 21 years and older based on 2005−2010 NHANES data (USEPA, 2019).

Parameter	Value	Units	Source
RSC	0.2	N/A	Based on a review of the available scientific literature on PFOS, potential exposure routes and sources exist but the available information is limited and does not allow for the quantitative characterization of the relative levels of exposure among these different sources (USEPA, 2024b).

Note: RfD = reference dose; DWI-BW = body weight-adjusted drinking water intake; HBWC = health-based water concentration; HFPO-DA = hexafluoropropylene oxide dimer acid; N/A = not applicable; NHANES = National Health and Nutrition Examination Survey; NTP = National Toxicology Program; RSC = relative source contribution.

[a] The RfD for PFOS is also based on the co-critical effect of decreased BWT in infants (Wikstrom et al., 2019; USEPA, 2024c). For the purposes of this calculation, the EPA based the MCLG on the co-critical effect of increased total cholesterol in adults in order to specify the target population needed for the selection of the DWI-BW term, which may change depending on the critical effect and critical study.

Additionally, establishing the MCLG for a chemical has historically been accomplished in one of three ways depending upon a three-category classification approach (USEPA, 1985; USEPA, 1991a). This approach was described in the proposed PFAS National Primary Drinking Water Regulation Rulemaking preamble (USEPA, 2023e). The starting point in categorizing a chemical is through assigning a cancer descriptor using the EPA's current *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005). Group C contaminants (USEPA, 1986) and contaminants with the descriptor of *Suggestive Evidence of Carcinogenic Potential* (USEPA, 2005) are in Category II. The EPA has historically set the MCLG for Category II contaminants based on noncancer effects, with the application of an additional modifying factor of 10 to account for uncertainties regarding the potential for carcinogenicity (USEPA, 1985; USEPA, 1991a). While not shown in the equation above, if the EPA were to derive a MCLG based on noncancer effects for PFOS, the EPA would consider this approach as well in order to ensure that the resulting MCLG includes an adequate margin of safety. The SAB also referred to this practice in their final report: "This approach is specified by USEPA (1985) for contaminants classified as "possible human carcinogens (Group C)" which is analogous to "suggestive evidence of carcinogenic potential" in the current terminology from the USEPA (2005) cancer risk assessment guidelines. An additional UF of 10 for potential carcinogenicity was incorporated into the RfDs for several USEPA MCLGs/MCLs including, for example, para-dichlorobenzene (USEPA, 1987)" (USEPA, 2022b).

Overall, the noncancer-based MCLG for PFOS would still be well below the MCL finalized in this rulemaking (4 ppt). Thus, there would be no change to the MCL for PFOS (see section V of the preamble and section 5 of the EPA response in this *Response to Comments* document for discussion on how the MCL is determined). Similarly, an MCLG for PFOA based on the noncancer RfD (3×10^{-8} mg/kg/day) would also be well below the MCL of 4 ppt:

$$\mathbf{MCLG} = \left(\frac{\text{RfD}}{\text{DWI-BW}}\right) * \text{RSC}$$

$$= \left(\frac{0.00000003 \ \frac{\text{mg}}{\text{kg/day}}}{0.034 \frac{\text{L}}{\text{kg/day}}} \right) * 0.2$$

$$= 0.0000002 \ \frac{\text{mg}}{\text{L}}$$

$$= 0.2 \ \frac{\text{ng}}{\text{L}} \text{ or parts per trillion (ppt)}$$

Table 4-2. PFOA Noncancer-Based MCLG – Input Parameters and Value

Parameter	Value	Units	Source
Chronic oral RfD[a]	3E-08	mg/kg/day	RfD based on co-critical effect of increased total cholesterol in adults (Dong et al., 2019; USEPA, 2024d).
DWI-BW	0.034	L/kg/day	90th percentile 2-day average, consumer-only estimate of combined direct and indirect community water ingestion for adults 21 years and older based on 2005−2010 NHANES data (USEPA, 2019).
RSC	0.2	N/A	Based on a review of the available scientific literature on PFOA, potential exposure routes and sources exist but the available information is limited and does not allow for the quantitative characterization of the relative levels of exposure among these different sources (USEPA, 2024a).

Note: RfD = reference dose; DWI-BW = body weight-adjusted drinking water intake; HBWC = health-based water concentration; HFPO-DA = hexafluoropropylene oxide dimer acid; N/A = not applicable; NHANES = National Health and Nutrition Examination Survey; NTP = National Toxicology Program; RSC = relative source contribution.

[a] The RfD for PFOA is also based on the co-critical effects of decreased BWT in infants and decreased antibody response to vaccination in children (Wikstrom et al., 2019; Budtz-Jorgensen and Grandjean (2018); USEPA, 2024d). For the purposes of this calculation, the EPA based the MCLG on the co-critical effect of increased total cholesterol in adults in order to specify the target population needed for the selection of the DWI-BW term, which may change depending on the critical effect and critical study.

Regarding the commenter's concern about the discussion on structural similarities between PFOA and PFOS, please see section 4.1.4 of the EPA response in this *Response to Comments* document. Regarding the commenter's concern that the toxicity assessments require a second round of peer review, please see section 4.1.3 of the EPA response in this *Response to Comments* document. Regarding the commenter's assertion that the findings of the toxicity assessment regarding the association between PFOS and kidney cancer contradict the EPA's economic analysis, please see sections 4.1.4 and 13.4 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-052922)

[The Agency's conclusion that PFOS is a likely carcinogen relies on reports of liver tumors in a single laboratory rat study that was previously determined to not provide sufficient evidence for such a conclusion. [FN6: USEPA. Proposed Approaches to the Derivation of a Draft Maximum

Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) (CASRN 1763-23-1) in Drinking Water. External Peer Review Draft. EPA Document No. 822D21002. Office of Water (2021). (USEPA Draft PFOS MCLG Approaches 2021)] These errors, further described below, combine to result in a flawed assessment by the Agency and overly stringent proposed MCL Goals and MCLs.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document, the EPA response to comment Doc. #1774, SBC-045684 and SBC-053190 in section 4.1.4.2 in this *Response to Comments* document, and the complete justification for the EPA's cancer classification for PFOS in Sections 3.5.5 and 5.4 of the final toxicity assessment (USEPA, 2024c).

American Chemistry Council (ACC) (Doc. #1841, SBC-052924)

The Human Data do not Support an Association Between PFOS Exposure and Increased Cancer Risk

Epidemiology studies have not reported a consistent or clear increase in cancers for occupational workers, impacted communities, or general population cohorts exposed to PFOS. The worker studies have focused on a fluorochemicals production facility in Alabama. Significant community studies include populations in France, Denmark, Sweden, Holland, Taiwan, and Greenland. These studies show no association of PFOS with liver, pancreatic, or prostate cancer or of cancers of the digestive, respiratory, lymphatic, or hematopoietic systems. While Alexander et al. (2003) reported an increase in bladder cancer in the worker population in Alabama, [FN27: Alexander et al. Mortality of employees of a perfluorooctanesulphonyl fluoride manufacturing facility. Occup Env Med 60:722-729 (2003).] a more detailed follow-up study found no association with bladder cancer and PFOS exposure. [FN28: Alexander BH and Olsen GW. Bladder cancer in perfluorooctanesulphonyl fluoride manufacturing workers. Ann Epidem 17:471-478 (2007).] No increase in breast cancer incidence was observed among 263 female employees at the production facility in Alabama, [FN29: Grice M et al. Self-reported medical conditions in perfluorooctanesulfonyl fluoride manufacturing workers. J Occup Environ Med 49(7):722–729 (2007).] although the number of cases was too small for further analysis.

No association with bladder, pancreatic, or liver cancer has been observed in non- occupational (community) studies of PFOS exposure. In fact, although EPA is inappropriately relying on Shearer et al. (2021) for their PFOA CSF, Shearer et al. also measured serum concentrations of PFOS and did not find an association with PFOS exposure and renal cell carcinoma (see Table 2 from Shearer et al. 2021). Eriksen et al. (2009) reported a possible increase in prostate cancer but no dose-response was observed, and the findings are not consistent with results from other studies. Notably, a case-control study of prostate cancer in Sweden suggests no association between PFOS exposure and risk of prostate cancer. [FN30: Hardell E et al. Case–control study on perfluorinated alkyl acids (PFAAs) and the risk of prostate cancer. Environment international, 63, 35-39. (2014).]

Several community studies have investigated the association with breast cancer and have reported mixed results, although the number of cases investigated in these studies has been relatively small. Two recent case-control studies have investigated the hormone receptor status among women with breast cancer in France and Taiwan. Both have suggested an association between PFOS exposure and estrogen receptor positive (ER+) tumors, the most commonly diagnosed tumor type. In both studies, the analysis was based on a single blood sample which, in the case of the study of French women, may have been collected several years before cancer diagnosis. PFOS levels vary widely between the two studies, with the blood collected in the Taiwan study between 2013 and 2015 – well after the voluntary phase out of PFOS in Japan, Europe, and the US. As a result, the relevance of the PFOS blood levels is uncertain. These studies are discussed below.

Mancini et al. (2020) investigated breast cancer incidence in 194 post-menopausal women (mean age of diagnosis – 68.8, range 58.3 to 84.9) diagnosed prior to 2013 for which a single blood sample had been collected between 1994 and 1999. [FN31: Mancini FR et al. Perfluorinated alkylated substances serum concentration and breast cancer risk: Evidence from a nested case-control study in the French E3N cohort. Intl J Cancer 146:917-928 (2020).] The association with ER+ tumors was only observed in adjusted Model 3 where the inclusion of so many covariables results in wide confidence intervals and limits the study's power. [FN32: Tumor hormone receptor expression was available for 158 of the 194 cases (81%). Of these, 132 tumors (83%) were ER+.] In a study of Taiwanese women, Tsai et al. (2020) observed an association between PFOS levels and the incidence of breast cancer overall and for ER+ tumors in woman less than 50 years old (mean age of 48.9 at diagnosis). [FN33: Tsai M-s et al. A case-control study of perfluoroalkyl substances and the risk of breast cancer in Taiwanese women. Environ Intl 142:105850 (2020).] Contrary to the results of the study by Mancini et al., there was no association with breast cancer or ER+ tumors in woman over the age of 50 – despite the fact these women were likely to have experienced higher overall exposure to PFOS.

EPA Response: The commenter incorrectly characterized the epidemiological evidence supporting an association between elevated exposure to PFOS and increased risk of cancer and asserted that epidemiological studies have not reported consistent evidence for several cancers (breast, bladder, liver, pancreatic, and prostate cancer; or cancers of the digestive, respiratory, lymphatic, or hematopoietic systems). Responses to these comments are provided in the EPA response to comment Doc. #1774, SBC-045684 and SBC-053187 in section 4.1.4.2 in this *Response to Comments* document. The EPA specifically refers the commenter to the discussion on recent studies reporting associations between PFOS serum concentrations and liver cancer in humans (see section 4.1.4 of the EPA response in this *Response to Comments* document). The commenter additionally raised concerns regarding the study selected for CSF derivation for PFOA (Shearer et al., 2021), which is discussed in the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683 in section 4.1.4.3 in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-044830)

Based on EPA's own cancer risk assessment guidelines, the animal data evaluating PFOS carcinogenicity are "suggestive", at best, not definitive, and are not supportive of a "likely" classification for human cancer risk. [FN34: USEPA. Cancer Risk Guidelines] Only one chronic animal bioassay has been performed with PFOS – Butenhoff et al. (2012). The study exposed Sprague-Dawley rats to up to 20 parts per million (ppm) K+PFOS in their diet for 2 years. [FN35: Butenhoff et al. Chronic dietary toxicity and carcinogenicity study with potassium perfluorooctanesulfonate in Sprague Dawley rats. Toxicol 293(1-3):1-15 (2012).] A recovery group was also exposed to the high dose diet for the first 52 weeks and then fed with control diet. Carcinogenic effects in the study included tumors in the liver, thyroid, and mammary gland. Pancreatic islet cell carcinomas increased among males, but not females, and the increase was not statistically significant for adenomas or combined adenomas or carcinomas. Despite being publicly available since 2012, EPA has never previously determined that the data from this rodent cancer bioassay were adequate to support the derivation of a CSF for PFOS. In 2016, the Office of Water concluded that "the weight of evidence for the carcinogenic potential to humans was judged to be too limited to support a quantitative cancer assessment." [FN36: USEPA PFOS HESD 2016, at ES-2.] Nothing has changed with these data and no additional evidence supporting derivation of a CSF for PFOS is available, thus it is unclear on which evidence EPA is now basing its determination.

For the pancreatic islet cell carcinoma observed in Butenhoff et al., the Office of Water did not include consideration of these tumors in its 2016 analysis of the health effects for PFOS. [FN37: USEPA. Drinking Water Health Advisory for Perfluorooctane Sulfonate (PFOS). EPA 822-R-16-004. Office of Water (May 2016). (USEPA PFOS HA 2016)] Similarly, these tumors were not included in the evidence the Office presented to the SAB in late 2021 in which the Water Office declined to consider PFOS a likely carcinogen. [FN38: USEPA Draft PFOS MCLG Approaches 2021, at 312.]

Thyroid and mammary tumors also were observed in the study by Butenhoff et al. Thyroid follicular cell tumors (adenomas in males, and adenomas/carcinomas combined in females) were significantly increased in recovery group males and in the second highest exposure group in females, but not in the other exposure groups including the high dose group. In females, mammary fibroadenomas and combined fibroadenomas/adenomas were increased over controls only in the lowest dose group and showed a significant negative trenI.

The inIreased incidence of total hepatocellular adenoma, statistically significant at the highest dose, was observed in both sexes in rats exposed for 2 years, but not 52 weeks. The increased incidence of hepatocellular adenomas in the male and female rats and of combined adenomas/carcinomas in the females, however, did not display a clear dose-related response. A statistically significant increase in the incidence of hepatocytic necrosis and hypertrophy in both males and females observed in this study and in other short-term studies, combined with evidence of PPARα and activation of other nuclear receptors, [FN39: Elcombe CR et al. Hepatocellular hypertrophy and cell proliferation in Sprague–Dawley rats from dietary exposure to potassium perfluorooctanesulfonate results from increased expression of xenosensor nuclear

receptors PPARα and CAR/PXR. Toxicol 293(1-3):16-29 (2012).] suggests that the liver tumors observed by Butenhoff et al. may be of limited relevance to humans. The authors concluded that the liver effects were consistent with activation of PPARα, constitutive androstane receptor (CAR), and pregnane X receptor (PXR) and that the available human and animal data "do not provide support for cancer risk from exposure to PFOS."

EPA's analysis suggests the potential for PFOS to induce hepatic tumors via multiple MOAs in rodents but provides only limited evidence to support other potential MOAs. The available data show that liver tumors in rats exposed to PFOS are likely caused by the activation of nuclear receptors, such as PPARα, CAR, and PXR. [FN40: See for example: Elcombe et al. 2012.] Despite the lack of a dose-response in tumor incidence and evidence to suggest the MOA is based on threshold response of nuclear receptors, the Agency develops a CSF based on linear, multiple stage modeling of the combined adenomas and carcinomas in the female rats. Although the available epidemiological and animal toxicity data may suggest a potential concern for carcinogenic effects in humans, the evidence is not sufficient for a stronger conclusion.

Overall, the rodent liver tumors from Butenhoff et al. are of questionable human relevance due to potential species-specific mode of action considerations (non-human relevant mechanisms involving xenobiotic nuclear receptors, such as PPARα); the liver tumors noted with statistical significance were benign adenomas; no statistically significant increases in hepatocellular carcinomas were observed in either the male or female rats and no clear dose response was noted. These data are not strong enough to suggest that PFOS is carcinogenic to humans at low doses, and do not support a linear low-dose extrapolation and MCL Goal of zero.

EPA Response: The commenter stated that the evidence related to the carcinogenicity of PFOS does not support a designation of *Likely to Be Carcinogenic to Humans* according to the EPA's guidance and provided several explanations underlying this assertion. The EPA disagrees with the explanations provided by the commenter, as described here and in responses to other commenters. Specifically, comments regarding the weight of evidence for the carcinogenic potential of PFOS and where this was described in the draft and final PFOS toxicity assessments (USEPA, 2023a; USEPA, 2024c), statistical significance of the pancreatic islet cell tumors in male rats (Thomford, 2002), rationale for the EPA updating the cancer classification for PFOS, the biological relevance of reporting tumor results at 52 weeks, the suggestion that MOAs related to nuclear receptor activation should be considered threshold effects, the human relevance of hepatocellular tumors resulting from PFOS administration, and the EPA's guidance on determining conclusions about the MOA for contaminants (USEPA, 2005) are discussed in the EPA responses to comment Doc. #1774, SBC-045684, SBC-053187, SBC-053190, and SBC-053196 in section 4.1.4.2 in this *Response to Comments* document. Additionally, please see section 4.1.4 of the EPA response in this *Response to Comments* document regarding the commenter's assertion that "no additional evidence supporting a derivation of a CSF for PFOS is available." The EPA reevaluated the data underlying the CSF for PFOS (i.e., the hepatocellular tumors in female rats) and the other information supporting the EPA's cancer classification for PFOS based on a recommendation by the SAB (USEPA, 2022b).

The commenter additionally stated that the increased incidence of hepatocellular tumors in the male and female rats did not display a dose-related response, though the EPA developed a CSF "based on linear, multiple stage modeling." The EPA disagrees with this comment. A biologically significant incidence of a rare tumor type (i.e., HCC) was observed in female rats (NTP, 2020) in the highest dose group and there was statistical evidence of a dose-related response. Both statistical and biological significance were considered when determining the cancer classification and selecting studies and endpoints for dose-response modeling. Male and female high dose groups had significantly increased incidences of hepatocellular tumors compared to the control groups and there were statistically significant positive trends of the responses in both sexes, clearly indicating a dose-response relationship. The observed dose-response relationship was also supported by the SAB PFAS panel who stated that "the interpretation of the hepatocellular carcinoma data from the Butenhoff (2012a) study in the 2016 HESD is overly conservative in dismissing the appearance of a dose-response relationship for this endpoint, particularly in females" (USEPA, 2022b). Further, for all studies, the dose-response relationship is at least partly an artifact of the study design and may be influenced by study design characteristics or observed results such as sample size, mortality, and other factors. These factors influence study sensitivity and may affect the response (or lack thereof) seen at lower dose levels. Without evidence demonstrating a threshold response and considering the EPA's determination that there may be multiple potential MOAs contributing to the carcinogenicity of PFOS, the EPA correctly assumed a linear low-dose response and relied on the preferred multistage models to derive CSFs based on animal toxicological studies for PFOS (USEPA, 2005; USEPA, 2012).

Mike Pettit (Doc. #1542, SBC-043345)

This leads into the next major issue that needs to be addressed: carcinogen risk. Consider the following section from page 96: "EPA reviewed the weight of the evidence and determined that PFOS is Likely to Be Carcinogenic to Humans, as "the evidence is adequate to demonstrate carcinogenic potential to humans but does not reach the weight of evidence for the descriptor Carcinogenic to Humans." This determination is based on the evidence of hepatocellular tumors in male and female rats, pancreatic islet cell carcinomas in male rats, and mixed but plausible evidence of bladder, prostate, kidney, and breast cancers in humans. As previously noted, the results provided by one chronic cancer bioassay in rats exceeds the descriptor of Suggestive Evidence of Carcinogenic Potential as it provides evidence of multi-site and multi-sex tumorigenesis. Consistent with the statutory definition of MCLG, EPA establishes MCLGs of zero for carcinogens classified as Carcinogenic to Humans or Likely to be Carcinogenic to Humans, described in Section V.A. of this preamble above as the linear default extrapolation approach. EPA has determined that PFOS is Likely to be Carcinogenic to Humans based on sufficient evidence of carcinogenicity in humans and animals and has also determined that a linear default extrapolation approach is appropriate as there is no evidence demonstrating a threshold level of exposure below which there is no appreciable cancer risk and therefore, it is assumed that there is no known threshold for carcinogenicity. Based upon a consideration of the best available peer reviewed science and a consideration of an adequate margin of safety, EPA

proposes a MCLG of zero for PFOS in drinking water.” This makes sense until it is taken in the context that this is based off a singular study that does provide some evidence that at 200 mg daily dose to a rat for two years will cause issues. One might as well consume the entirety of a plastic 2-liter bottle every day, only to be surprised in several months that apart from crippling liver and kidney failure, there is also cancer potentially in their body now. The claim is obviously absurd. The sheer level of exposure should then be correlated to the toxicity equivalent for humans. A problem exists also in extrapolating from animal studies to humans can be problematic due to differences in the way humans and animals metabolize and eliminate chemicals. While one animal study has shown that PFAS exposure can cause tumors, others have not found a clear link between PFAS and cancer. For example, one study of workers exposed to PFOA found no increase in cancer risk, while another study of exposed workers found a possible association with prostate cancer but no clear evidence of an increased risk of other types of c’ncer. It's also worth noting’that EPA's designation of‘PFOS as "likely to be carcinogenic ”o humans" is not based on direct evidence of carcinogenicity in humans. R’ther, it's based on evidence of hepatocellular tumors in male and female rats, pancreatic islet cell carcinomas in male rats, and mixed but plausible evidence of bladder, prostate, kidney, and breast cancers in humans. The extrapolation of this evidence to humans is a complex process, and there are inherent uncertainties and limitations in such extrapolations.

Disregarding the issue that the dosage volumes have no extrapolation/correlation data given between rats and humans, the bigger issue lies within the fact there is only one study being used to lay the foundation of this classification. It is common practice that studies indicating something should be duplicated to ensure not only the integrity of the study, but also to add to the body of evidence to support the findings in the original study. The reason is obvious- studies need to be verified before full conclusions can be drawn so that appropriate civil actions can be enacted upon. This is not the case in the memo passed from the EPA. Therefore, drawing up the title “Likely to Be Carcinogenic to Humans” has only the basis of one study and is erroneously applied. No further duplication and verification of the findings in the original paper have been used or even cited, and this results in a premature label being added. Corrective action should be immediately taken to rectify this egregious error.

Something important to note, a threat of cancer is a fact of life for the most basic aspects of living. As anyone who has taken any form of biological class would know, cancer is merely a label for an aberrant cell that no longer functions in the way that a normal cell would. Cancerous cells are not even always inherently dangerous (which may be a shock to some). The creation of these incorrect cells occurs daily. These same cells are dealt with daily. Every person, creature, thing with more than 10 cells making up its body deals with cancer every single day. Anything and everything that can cause aberrations in making normal cells could technically be labeled as carcinogenic. Therefore using the term “cancer causing” on something that is normally nonreactive with minimal scientific evidence behind it is absurd. The lack of evidence is overwhelming and can only be used to stir up people who honestly do not know any better. It is clickbait in the first degree.

EPA Response: The commenter disagrees with the EPA's conclusions about the carcinogenic potential of PFOS. However, the commenter appears to misunderstand the EPA guidance related to carcinogens and fundamental concepts underlying these assessments, including the extrapolation from animal toxicological data to human exposure. Additionally, the EPA disagrees with the commenter's statements regarding the strength of evidence supporting the EPA's cancer classifications for PFOA and PFOS. Rebuttal to these comments is provided in the EPA response to comment Doc. #1774, SBC-045684, SBC-053187, SBC-053190, and SBC-053196 about PFOS in section 4.1.4.2 in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683 about PFOA in section 4.1.4.3 in this *Response to Comments* document. For PFOS, evidence from recently published epidemiological studies show concordant associations between PFOS serum concentrations and HCC in humans (Goodrich et al., 2022; Cao et al., 2022), further supporting the evidence of hepatocellular tumors in animal models.

With respect to the designation of PFOS as *Likely to Be Carcinogenic to Humans*, the commenter is incorrect in stating that the designation is based on a singular study. As described in section 3.5 of the PFOS toxicity assessment (draft (USEPA 2023a) and final (USEPA, 2024c)), the cancer classification is supported by human, animal and mechanistic evidence, consistent with the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005). Importantly, the available mechanistic evidence supports the EPA's conclusion that multiple human relevant MOAs are operative in the hepatic and pancreatic tumorigenesis associated with PFOS exposure based on animal model study findings. Similarly, the International Agency for Research on Cancer (IARC) (Zahm et al., 2023) concluded that there is strong mechanistic evidence of carcinogenicity in exposed humans and that PFOS is immunosuppressive and induces epigenetic alterations in humans, induces oxidative stress in human primary cells and experimental systems and modulates multiple receptors. As described in the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005), "[i]n the absence of sufficiently, scientifically justifiable mode of action information, EPA generally takes public health-protective, default positions regarding the interpretation of toxicologic and epidemiologic data; animal tumor findings are judged to be relevant to humans, and cancer risks are assumed to conform with low dose linearity." The available mechanistic data does not support a single, scientifically justified MOA for PFOS-induced hepatic and pancreatic carcinogenesis; in fact, there is evidence supporting the potential for multiple plausible MOAs (USEPA, 2005). Therefore, the EPA followed its guidance in judging that the animal tumors are relevant to humans.

The EPA agrees that there can be uncertainties associated with the extrapolation of data from animal models to humans (see section 4.2.2 of the EPA response in this *Response to Comments* document), including several that the commenter highlighted above (e.g., toxicokinetic differences between species). However, the EPA disagrees that this precludes the agency from quantitatively relying on studies in animal models for the derivation of toxicity values. This practice has been used to support agency risk assessments for decades and has been repeatedly endorsed by agency guidance and methods (USEPA, 2002; USEPA, 2005; USEPA, 2014a; USEPA, 2022a). The EPA agrees that extrapolation from animal models to humans is complex,

but animal toxicological studies, regardless of study design characteristics such as dose levels, can be used to determine potential human health hazards and the exposure levels and internal doses (e.g., serum concentrations) that may be expected to cause adverse health effects in humans. With an understanding of how the chemical may behave differently in animals and humans (e.g., differences in excretion rates), the EPA can estimate the equivalent level of exposure that would pose a risk to human health and compare those values across any effects that could pose a hazard. In this way, the EPA can determine the minimum exposure level (e.g., RfD) that could result in a risk to human health. The pharmacokinetic approach the EPA used to estimate human equivalence doses from animal toxicological studies is available in Section 4.1.3 of the PFOA and PFOS toxicity assessments and is discussed further in Section 4.2.4 of this response to public comments document (USEPA, 2024d; USEPA, 2024c).

Finally, regarding the commenter's statement that "a threat of cancer is a fact of life for the most basic aspects of living," the EPA does not agree that exposure to cancer-causing agents in our drinking water is "imply a "basic aspect of living." The SDWA requires the EPA to set an MCLG at "a level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety" and the MCL be set at a level "as close as feasible" to the MCLG. The EPA is committed to providing Americans clean, safe drinking water, consumption of which should not cause undue risk to the health of persons. While cancer may impact Americans every day, exposure to harmful contaminants through drinking water should not increase that burden, and through the finalization of this PFAS NPDWR, the EPA anticipates meaningful reduction of cancer risk for millions of Americans.

PFAS Regulatory Coalition (Doc. #1761, SBC-046070)

B. The science does not support EPA's new classification of PFOS as a likely carcinogen.

In the Proposal, EPA has determined for the first time that PFOS is a likely carcinogen. EPA states that it has reviewed the weight of the evidence and determined that PFOS is Likely to Be Carcinogenic to Humans, as ''the evidence is adequate to demonstrate carcinogenic potential to humans but does not reach the weight of evidence for the descriptor Carcinogenic to Humans.'' 88 Fed Reg. 18663. Yet, before this Proposal, EPA had determined that PFOS was not a likely carcinogen, and it is not clear what "best available science" EPA is considering now in order to reach this new conclusion. Absent proper scientific support, EPA's new interpretation of largely the same data to reach different conclusions is arbitrary and capricious. EPA actually states at one point that reports preclude a definitive conclusion, but then in the next sentence, EPA points to only "one high confidence" study that found "associations" between PFOS and cancer before concluding that "available study findings support a plausible correlation between PFOS exposure and carcinogenicity in humans." 88 Fed. Reg. 18660, 18710.

It appears that EPA changed its classification of PFOS from "Suggestive Evidence of Carcinogenic Potential" to "Likely to be Carcinogenic to Humans" following the EPA Science Advisory Board's review of EPA's "Draft Proposed Approaches to the Derivation of a Draft

Maximum Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) (CASRN 1763-23-1) in Drinking Water." The SAB says: "The magnitude of the association between PFOS and kidney cancer was lower than that for PFOA, and after adjustment for other PFAS, the adjusted OR for the highest quartile was 1.14 and not statistically significant. However, these data should be presented clearly including a discussion of why the PFOS data from Shearer et al. (2021) were not considered sufficient for a higher designation of 'likely carcinogenic.'" Science Advisory Board Report, "Review of EPA's Analyses to Support EPA's National Primary Drinking Water Rulemaking for PFAS," at 36 (Dkt. No. EPA-HQ-OW-2022-0114-0078) (SAB Report).

The article referred to by the SAB Report is "Serum Concentrations of Per- and Polyfluoroalkyl Substances and Risk of Renal Cell Carcinoma," Shearer, J., et al., Journal of the National Cancer Institute, vol. 113, issue 5 (2021), at 580 (Dkt. No. EPA-HQ-OW2022-0114-0847). It is notable that the abstract for this article says:

"It remains unclear whether PFOA or other PFAS are renal carcinogens or if they influence risk of renal cell carcinoma (RCC) at concentrations observed in the general population."

Rather than improving the discussion of Shearer, et al. (2021), as recommended by the SAB, and despite the authors' conclusion quoted above, EPA's response to the SAB shows that EPA instead relied on this article to change its classification of PFOS to a "Likely Carcinogen." EPA Response to Final Science Advisory Board Recommendations (August 2022) on Four Draft Support Documents for the EPA's Proposed PFAS National Primary Drinking Water Regulation, at 26 (Dkt. No. EPA-HQ-OW-2022-0114-0043). That reliance, and the resulting determination of likely human carcinogenicity, are not supported by the best available science and not justified based on statements in that article itself.

In the Proposal, EPA concedes that scientific uncertainties exist surrounding the effects of PFOS exposure: "The available epidemiology studies reported elevated risk of bladder, prostate, kidney, and breast cancers after chronic PFOS exposure. While there are reports of cancer incidence from epidemiological studies, the study designs, analyses, and mixed results preclude a definitive conclusion about the relationship between PFOS exposure and cancer outcomes in humans." 88 Fed. Reg. at 18660. Also, EPA's Health Effects Support Document for Perfluorooctane Sulfonate (PFOS) EPA 822-R-16-002 states: (i) "Several human epidemiology studies evaluated the association between PFOS and cancers including bladder, colon, and prostate, but these data present a small number of cases and some are confounded by failure to adjust for smoking. The associations for most epidemiology endpoints are mixed," (ii) "The genotoxicity data are uniformly negative," (iii) "Human epidemiology studies did not find a direct correlation between PFOS exposure and the incidence of carcinogenicity in worker-based populations." In fact, results were so inconclusive that EPA cited 11 studies showing no association between increased serum PFOS and various types of cancer, and an additional two studies that showed a negative association between serum PFOS and breast or uterine cancer, indicating protective effect.

Facing this lack of clear evidence from human studies, EPA turned to one animal study for evidence of carcinogenicity in humans, as stated in the Proposal: "The one high confidence animal chronic cancer bioassay study provides evidence of multi-site tumorigenesis in both male and female rats" and the "single chronic cancer bioassay performed in rats is positive for multi-site and -sex tumorigenesis (Thomford, 2002; Butenhoff et al., 2012b)." 88 Fed. Reg. 18638. These statements do not support the conclusion that "evidence is adequate" as to human carcinogenicity. Moreover, observations of tumorigenesis in laboratory animals dosed at PFAS levels that are environmentally immaterial is not tantamount to risk of cancer in the general human population. Direct extrapolation down to 4 ppt (effectively the reporting limit for PFAS in water), based on animals dosed at PFAS levels much higher than those observed in the Unregulated Contaminant Monitoring Rule

3 (UCMR3) study is inconsistent with an understanding of human physiology and dictates a dose-response curve that is unsupported by science.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document regarding how the EPA reached the conclusion that PFOS is *Likely to Be Carcinogenic to Humans*, in accordance with the Guidelines for Carcinogen Risk Assessment (USEPA, 2005). The EPA disagrees with the commenter's other erroneous claims and rationale and has provided rebuttals in section 4.1.4 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045684, SBC-053187, SBC-053190, and SBC-053196 in section 4.1.4.2 in this *Response to Comments* document. The EPA also discusses uncertainties with the extrapolation of data from animal models to humans in the EPA response to comment Doc. #1542, SBC-043345 above.

Regarding evidence supporting the association between PFOA and kidney cancer, please see the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683 in section 4.1.4.3 in this *Response to Comments* document. A single study was not used to support the agency's conclusions that PFOA exposure is associated with increased risk of kidney cancer in humans, nor is the commenter correct in stating that the EPA relied on Shearer et al. (2021) to update the cancer descriptor for PFOS (see section 4.1.4 of the EPA response in this *Response to Comments* document).

NCASI (Doc. #1651, SBC-043215)

In the proposed rulemaking, EPA has determined that PFOS is a likely carcinogen. EPA states "the evidence is adequate to demonstrate carcinogenic potential to humans but does not reach the weight of evidence for the descriptor Carcinogenic to Humans." (pg. 18663). As recently as in 2021, as noted in the "Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) in Drinking Water; Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctanesulfonic Acid (PFOS) in Drinking Water", EPA had determined that the PFOS MCLG should be based on a non-carcinogenic endpoint , and it is not clear what new

information EPA is considering in order to make this new conclusion. EPA relies on "one high confidence" study before concluding that "available study findings support a plausible correlation between PFOS exposure and carcinogenicity in humans." (pg. 18660).

EPA's determination is put in the context of the scientific uncertainties that exist when evaluating the potential carcinogenicity of PFOS: "The available epidemiology studies reported elevated risk of bladder, prostate, kidney, and breast cancers after chronic PFOS exposure. While there are reports of cancer incidence from epidemiological studies, the study designs, analyses, and mixed results preclude a definitive conclusion about the relationship between PFOS exposure and cancer outcomes in humans." There are additional sources of substantive uncertainty cited in EPA's Health Effects Support Document for Perfluorooctane Sulfonate (PFOS) EPA 822-R-16-002 that indicates: "Several human epidemiology studies evaluated the association between PFOS and cancers including bladder, colon, and prostate, but these data present a small number or cases and some are confounded by failure to adjust for smoking. The associations for most epidemiology endpoints are mixed,"; "The genotoxicity data are uniformly negative,"; and "Human epidemiology studies did not find a direct correlation between PFOS exposure and the incidence of carcinogenicity in worker-based populations."

The single animal study relied upon by EPA for the carcinogenicity of PFOS is described as: "The one high confidence animal chronic cancer bioassay study provides evidence of multi-site tumorigenesis in both male and female rats" and "The single chronic cancer bioassay performed in rats is positive for multi-site and -sex tumorigenesis" (pg. 18638)12 [FN1: Thomford, P. 2002. 104-Week Dietary Chronic Toxicity and Carcinogenicity Study with Perfluorooctane Sulfonic Acid Potassium Salt (PFOS; T–6295) in Rats (pp. 1–216). 3M. Available on the internet at: https://www.ag.state.mn.us/Office/Cases/3M/docs/PTX/PTX2805. pdf] [FN2: Butenhoff, J.L., Chang, S.C., Olsen, G.W., and Thomford, P.J. 2012. Chronic Dietary Toxicity and Carcinogenicity Study with Potassium Perfluorooctane Sulfonate in Sprague Dawley Rats. Toxicology, 293:1– /doi.org/10.1016/j.tox.2012.01.003] This limited evidence is not sufficient to support the conclusion that "evidence is adequate" as to human carcinogenicity, particularly when considering that these observations of tumorigenesis are in excess of environmentally relevant concentrations of PFOS.

While EPA indicates that that these conclusions were arrived at with a systematic review, it is not clear whether the systematic review protocol was adequately developed to appropriately apply the noted sources of uncertainty into the conclusion of carcinogenic classification. Many of these issues could have been addressed by peer review/public comment on the systematic review protocol used in the MCL development. It is common practice among regulatory agencies to either publish or distribute for comment a proposed protocol that can be revised based on technical feedback as seen in other EPA program areas such as the Integrated Risk Information System (IRIS). Not only does this serve to enhance the transparency of the review process, but also provides additional perspectives on many of the criteria for risk of bias and evidence integration that must be detailed a priori to the actual review. NCASI supports the opportunity to provide technical comments on proposed systematic review protocols.

EPA Response: Regarding comments on the carcinogenicity assessment for PFOS, please see section 4.1.4 of the EPA response in this *Response to Comments* document and EPA response to comment Doc. #1774, SBC-045684, SBC-053187, SBC-053190, and SBC-053196 in section 4.1.4.2 in this *Response to Comments* document. Regarding comments on the systematic review protocol, please see section 4.1.1 of the EPA response in this *Response to Comments* document. Regarding comments on the peer review process for this rulemaking, please see section 4.1.3 of the EPA response in this *Response to Comments* document. Briefly, the EPA followed the agency's *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) in determining that PFOS is *Likely to Be Carcinogenic to Humans*. The EPA additionally notes that the systematic review protocol for the toxicity assessments was released for public comment as Appendix A of the *Public Comment Draft Toxicity Assessments and Proposed Maximum Contaminant Level Goals for PFOA and PFOS in Drinking Water* (USEPA, 2023b; USEPA, 2023c).

Washington State Department of Health (DOH) (Doc. #1665, SBC-044408)

While there is solid evidence that PFOS is a rodent carcinogen, there is currently only weak and inconsistent epidemiological evidence that PFOS has caused cancer in humans. EPA classification of PFOS as a likely human carcinogen is reasonably supported by mechanistic data showing PFOS to have several characteristics of carcinogens, structural similarity to PFOA, and functional similarity to PFOA on other health endpoints.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045684, SBC-053187, SBC-053190, and SBC-053196 in section 4.1.4.2 in this *Response to Comments* document regarding the strength of the epidemiological evidence supporting the cancer classification for PFOS. The EPA also directs the commenter to Sections 3.5.5 and 5.4 of the final toxicity assessments for PFOS which outline the rationale for the EPA's cancer classification for PFOS (USEPA, 2024c), which is based on recommendations from agency guidance (USEPA, 2005). The commenter provides additional supporting comments for other factors considered in the cancer assessment.

City of Vancouver Water Utility, Vancouver, WA (Doc. #1684, SBC-044305)

Is there clear evidence that PFOS is a human carcinogen? While there is solid evidence that PFOS is a rodent carcinogen, there is currently only weak and inconsistent epidemiological evidence that PFOS has caused cancer in humans.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045684, SBC-053187, SBC-053190, and SBC-053196 in section 4.1.4.2 in this *Response to Comments* document.

4.1.4.3 Comments Specific to PFOA

Provencher Engineering, LLC (Doc. # 1564, SBC-042504)

More recently, the New Hampshire Department of Health and Human Services (NHDHHS) has conducted two important studies. One is a "MVD Community Exposure Assessment Report" (NHDHHS summary attached), which included PFOA blood sampling of 217 random MVD customers, which concluded that the average MVD customer's blood PFOA was 4 ug/L, double the national average of 2 ug/L from 2013-2014 (please refer to attached summary report). The second is a "Cancer Incidence Report for Merrimack, NH, January 2023" (attached), which based on Table 3 in that report, indicates a Standard Incidence Report (SIR) value for Merrimack, NH of 1.42, meaning that there is a 42% greater incidence of Kidney and Renal Pelvic cancers as compared to the rest of the state! That's what Table 3 represents, as presented by the DHHS itself. Combining the implications of the facts that: (1) Merrimack, NH is one of the worst cases of widespread PFOA contamination in the country due to air borne PFAS emissions from one or more polluters in and adjacent to Merrimack, that: (2) MVD customers' blood PFOA is double the national average, and that: (3) The Cancer Incidence Report in Merrimack indicates 42% more pelvic & renal cancers, it requires the application of common sense to be applied. These are not merely coincidences! It's time to take actions to reduce PFAS exposures, which includes treating more PFAS contaminated drinking water!

EPA Response: The commenter provided two reports which described the efforts of the New Hampshire Department of Health and Human Services (NHDHHS) to characterize PFAS exposure and associated cancer incidence in Merrimack, NH as evidence supporting the EPA's cancer assessment for PFOA. Given the EPA's cancer classification for PFOA and the resulting MCLG of zero, the EPA agrees that the available evidence indicates that there is no dose below which PFOA is considered safe in regard to cancer risk. Further, the EPA reviewed the information provided by the commenter regarding PFAS exposure and cancer incidence in Merrimack, NH (see section 4.2.6 of the EPA response in this *Response to Comments* document regarding how the EPA considered literature recommended in public comments). The EPA has identified a related peer-reviewed publication post-dating the updated 2022 literature search conducted prior to rule proposal (Messmer et al., 2022) that presents results from the NHDHHS report cited in this comment. The study findings and assessment implication for Messmer et al. (2022) has been added to the table of studies identified after the updated 2022 literature search (USEPA, 2024a, Sec. A.3). The ecological design of the study limits its utility for dose-response analysis; however, the report and associated publication (Messmer et al., 2022) are coherent with the EPA's conclusions that PFOA is *Likely to Be Carcinogenic to Humans* and that elevated PFOA exposure is associated with an increased risk of renal cancer.

3M Company (Doc. #1774, SBC-045682 & SBC-045683)

The MCLG of zero for PFOA is based on EPA's determination that PFOA is "likely to be carcinogenic to humans." EPA's conclusion is reportedly based on evidence of kidney and

testicular cancer in humans and testicular Leydig cell tumors ("LCTs"), pancreatic acinar cell tumors, and hepatocellular adenomas in rats. As discussed below, as a result of process failures, EPA's analysis of the evidence on which it relies is fundamentally flawed, rendering EPA's conclusion unreliable.

In determining whether a substance is a likely carcinogen, EPA follows its Guidelines for Carcinogen Risk Assessment (USEPA 2005). That Guidance directs EPA to evaluate relevant studies and make a "weight of evidence" determination, by "weighing all of the evidence in reaching conclusions about the human carcinogenic potential of agents" based on considerations of animal and human evidence, mechanisms of action and dose-response relationships (USEPA 2005, p. 1-11). Here, EPA's systematic review and evidence synthesis failures led it to inaccurately assess the weight of the evidence as it relates to PFOA. For example, tumors identified in animals have questionable relevance to humans because they have been shown to occur through the PPARα pathway, a mode of action with limited relevance to humans (Biegel et al., 2001; Corton et al., 2018). In addition, the LCT tumors observed in animals do not have a common mode of action with testicular germ cell tumors seen in humans (Klaunig et al. 2012). Additionally, an excess of renal tumors has not been reported in three rat studies (NTP 2020; Butenhoff et al. 2012; Biegel et al. 2001).

Despite the limited supporting evidence for renal carcinogenicity in animal studies, EPA relied primarily on the matched case-control study on kidney cancer (Shearer et al. 2021), even though other studies on humans evaluating associations between kidney cancer and PFOA exposure also have yielded inconsistent results and do not demonstrate consistent dose-response (Steenland and Woskie 2012; Barry et al. 2013; Raleigh et al. 2014).

Moreover, the study by Shearer et al. (2021) relied upon by EPA to derive the cancer slope factor (CSF) [FN58: A cancer slope factor is a value representing a relationship between increases in exposure dose and cancer risk.] for PFOA is undermined by the study's reliance on PFOA exposure measured at a single point in time almost a decade before cancer diagnosis. This discrepancy adds uncertainty to the associations of exposure and cancer outcomes, as discussed in more detail below. Furthermore, Shearer et al. (2021) insufficiently adjusts for confounding by key risk factors, including the very limited categorical data on smoking history, body mass index, and history of hypertension. EPA's Guidelines for Carcinogen Risk Assessment (2005) specifically discusses the importance of confounding factors and states, "[c]ommon examples include age, socioeconomic status, smoking habits, and diet" and further "[s]tatistical analyses of the bias, confounding, and interaction are part of addressing the significance of an association and the power of a study to detect an effect." EPA failed to follow its guidance when using Shearer et al. (2021) without consideration of these important variables.

Contrasts in PFOA levels in this study cohort were also modest—comparing the upper quartile of >7.3 µg/L PFOA to a lower quartile of <4.0 ug/L PFOA—and substantially smaller than exposure contrasts in more highly exposed populations that showed no significant difference in kidney cancer risk (e.g., Raleigh et al. 2014). The reference group (i.e., the least exposed group) in Shearer et al. (2021) also had fewer cases (47 cases) than the control group (81 controls),

which may have biased the statistical comparisons for the other exposure categories. This distribution of 81 controls and only 47 cases in the referent group is counterintuitive because one would expect a more similar distribution among the least exposed. Neither Shearer et al. nor EPA commented on this referent group, which becomes the main driver in the subsequent calculations for the other three exposure categories. This shortcoming another example of EPA's attempts to infer statistical properties as discussed in Section IV.b. Other scientific literature indicates no association between PFOA exposure and kidney cancer risk; for example, a significant association or exposure-response trend was not observed between PFOA exposure and kidney cancer incidence or mortality in several other human epidemiological studies, including those from highly exposed occupational cohorts (e.g., Barry et al. 2013; Raleigh et al. 2014). The fact that there was little to no association between exposure to PFOA in workers with occupational exposure to high levels of PFAS and kidney cancer should have been considered by EPA as strong evidence against carcinogenicity, but , as a result of its deficient review processes, EPA appears to have largely disregarded this evidence.

Finally, the mechanistic weight of evidence for carcinogenicity indicates that PFOA is more likely to act via a threshold mode of action. EPA concludes that "most of the evidence for mutagenicity is consistently negative." This means that best practice would be for EPA to identify a dose below which toxicity does not occur (the threshold) and, accordingly, set an MCLG based on that dose (rather than assuming a zero MCLG). EPA's overall conclusions, however, assume a linear-no threshold model of carcinogenicity based on default assumptions of EPA's Cancer Guidelines (USEPA 2005) rather than analysis of the weight of evidence. As detailed in the section below on evidence of PFOS carcinogenicity, many of the modes of action for carcinogenicity of PFOA identified in animals do not apply to humans (e.g., PPARα pathways) and best practice dictates that EPA's assessment of carcinogenic mode of action should be revised to reflect its conclusion that most of the evidence for mutagenicity is consistently negative, indicating the linear no-threshold model of carcinogenicity is not appropriate for PFOA.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document. The commenter stated that the process and evidence the EPA used to determine that PFOA is *Likely to Be Carcinogenic to Humans* were flawed. The EPA disagrees with this statement because the EPA relied on Agency methodology to systematically identify, evaluate, and synthesize literature relevant to the carcinogenicity of PFOA, as well as determine the weight of evidence across epidemiological, animal toxicological, and mechanistic studies (USEPA, 2022a). The full protocols the EPA used to identify and synthesize relevant studies were available at the time of public comment as Appendix A of the toxicity assessments (USEPA, 2023b; USEPA, 2023c). These are consistent with systematic review protocols published in the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a) and the *Systematic Review Protocol for the PFBA, PFHxA, PFHxS, PFNA, and PFDA (anionic and acid forms) IRIS Assessments* (USEPA, 2021a). The EPA followed the *Guidelines for Carcinogen Risk Assessment,* including the Mode of Action Framework, to determine the weight of evidence of carcinogenicity for PFOA from epidemiological, animal toxicological, and mechanistic studies

(USEPA, 2005). The commenter did not provide any additional studies that the EPA did not evaluate and document in its assessment. Responses to the commenter's specific comments are provided below. Regarding the commenter's asserted "process failures," please see section 4.1.2 of the EPA response in this *Response to Comments* document.

The commenter asserted that tumors identified in animals have "questionable relevance" to humans, that there are differences in MOAs of testicular tumors observed in rats and humans, and that renal tumors observed in epidemiological studies were not reported in studies of rats. The EPA discussed hypothesized and alternative MOAs for all tumor types reported in the epidemiological and animal toxicological literature in Section 3.5.4.2 of the PFOA toxicity assessment (USEPA, 2023f). Additionally, the EPA stated particularly for the PPARα activation MOA for hepatic tumors, which is generally understood to operate in a species-specific manner: "for PPARα activators that act solely or primarily through PPARα-dependent mechanisms (e.g., Wyeth-14,643 or di-2-ethyl hexyl phthalate), the hepatic tumorigenesis observed in rodents is expected to be infrequent and/or less severe in humans, or not observed at all {Klaunig, 2003, 5772415; Corton, 2014, 2215399; Corton, 2018, 4862049}." However, after review of the available literature, the EPA determined that "PFOA exposure is associated with several mechanisms that can contribute to carcinogenicity, including epigenetic changes and oxidative stress, which may occur in conjunction with or independently of PPARα activation. It is plausible that these mechanisms may occur independently of PPARα-dependent mechanisms. These observations are consistent with literature reviews recently published by state health agencies which concluded that the hepatotoxic effects of PFOA may not entirely depend on PPARα activation (CalEPA, 2021; NJDWQI, 2017; USEPA, 2023f; USEPA, 2024d). Moreover, IARC recently concluded there is strong mechanistic evidence of carcinogenicity in exposed humans and that PFOA is immunosuppressive, induces epigenetic alterations, induces oxidative stress, modulates receptor-mediated effects (via PPARα, CAR/Pregnane X Receptor (PXR), and PPARγ), and alters cell proliferation, cell death, and nutrient and energy supply (Zahm et al., 2023). The existence of multiple MOAs in addition to PPARα activation suggest that PFOA-induced liver cancer in rats may be more relevant to humans than previously thought. The EPA also noted that the evidence supporting the claim that PPARα agonism mediates tumorigenesis for the two other tumor types observed in animal species, pancreatic acinar cell tumors and Leydig cell tumors (LCTs), is limited and "not as strong as for other tumor types (i.e., hepatic tumors)." When conducting its assessment, the EPA considered all potential MOAs and underlying carcinogenic mechanisms, not just PPARα activation. The EPA discusses additional hypothesized MOAs that may be human relevant and may contribute to the hepatic, pancreatic, and testicular tumors observed in rodents in Section 3.5.4.2 of the final toxicity assessment (USEPA, 2024d). The commenter is also referred to the EPA response to comment Doc. #1774, SBC-053196 in section 4.1.4.2 in this *Response to Comments* document for discussion on the MOAs for PFOS that are also relevant to PFOA.

The commenter stated that LCTs "observed in animals do not have a common MOA with testicular germ cell tumors seen in humans." This statement is not demonstrably accurate because the MOAs for these tumors in humans or animals have not been determined; thus, it is

actually not clear whether the testicular tumors observed in humans and animals do not share an MOA or mechanism of action. Regardless, the EPA does not agree that this is a factor that would detract from conclusions regarding the carcinogenic potential of PFOA. The EPA's MOA analysis for LCTs (see Section 3.5.4.2.2, USEPA, 2024d) evaluated the evidence for six MOAs. Evidence from rodent studies supported hypotheses that PFOA may cause testicular tumorigenesis through some of these human-relevant MOAs (i.e., aromatase inhibition, estrogen agonism, and testosterone biosynthesis inhibition), and lacked evidence supporting other MOAs (i.e., 5α-reductase inhibition and androgen receptor antagonism). The available evidence does not indicate a singular, common MOA to explain the LCTs in animals but indicates that PFOA exposure leads to several key events across multiple MOAs. The EPA also notes in the assessment that "it is unclear whether these MOAs are relevant to testicular cancers associated with PFOA exposure in humans," owing in part to a lack of mechanistic data from human PFOA studies of testicular tumors (USEPA, 2024d). Further, the following text has been added to the final assessment (USEPA, 2024d) to clarify that although Clegg et al. (1997) concluded human relevance of several of these MOAs, the sensitivity varies across species: "The working group noted that sensitivity for the initiating events in these MOAs varies across species, with rodents being more sensitive relative to humans." Testicular tumors were observed in rodents at doses as low as 13.6 mg/kg/day after two years. Changes in key events in the LCT MOAs were observed at even lower doses (as low as 1 mg/kg/day), though many of the studies at lower doses were conducted for durations too short to measure tumor formation (e.g., 16 weeks); had those studies been extended to two years, more tumor incidence may have been observed. Finally, the EPA also notes that "site concordance is not always assumed between animals and humans," meaning that the occurrence of LCTs in rodents may not necessarily translate directly to the occurrence of testicular tumors in humans (USEPA, 2005). The observation of LCTs in rodents reflects more on the potential carcinogenic potency of PFOA, and not necessarily a particular tumor type expected to occur in humans.

The commenter also stated that renal tumors were not observed in three studies in rats. The EPA does not agree that this is a finding that detracts from conclusions regarding the carcinogenic potential of PFOA. It is important to note that the *Guidelines for Carcinogen Risk Assessment* also state that, "there is evidence that growth control mechanisms at the level of the cell are homologous among mammals, but there is no evidence that these mechanisms are site concordant. Moreover, agents observed to produce tumors in both humans and animals have produced tumors either at the same site (e.g., vinyl chloride) or different sites (e.g., benzene) (NRC, 1994). Hence, site concordance is not always assumed between animals and humans" (USEPA, 2005). The *Guidelines* further note, "positive effects in animal cancer studies indicate that the agent under study can have carcinogenic potential in humans… The option is supported by the fact that nearly all of the agents known to cause cancer in humans are carcinogenic in animals in tests that have adequate protocols (IARC, 1994; Tomatis et al., 1989; Huff, 1994)." Additionally, "[i]n the absence of sufficiently, scientifically justifiable mode of action information… animal tumor findings are judged to be relevant to humans" (USEPA, 2005). Given this guidance and the use of methods consistent with current best practices (USEPA,

2022a), the EPA correctly evaluated the weight of evidence across human, animal, and mechanistic data to inform its determination that PFOA is *Likely to Be Carcinogenic to Humans.*

The commenter cited three epidemiological studies of renal cancer (Steenland and Woskie 2012; Barry et al. 2013; Raleigh et al. 2014) that they claimed showed "inconsistent results." This claim is misleading. One of these studies was determined to be *low* confidence primarily because it lacked direct or modelled exposure to PFOA and is further discussed later in this response (Raleigh et al., 2014). Steenland and Woskie (2012) and Barry et al. (2013) both reported positive trends for kidney cancer (significant in Steenland and Woskie (2012)), which is consistent with the EPA's conclusions regarding associations between kidney cancer and PFOA exposure. In contrast to the commenter's claims, Barry et al. (2013) concluded, "PFOA exposure was associated with kidney and testicular cancer in this population." Furthermore, the commenters failed to acknowledge another *medium* confidence study that reports increases in kidney cancer with PFOA exposure (Vieira et al., 2013), a meta-analysis that also reports a positive association (Bartell et al., 2021), the recently published pooled analysis (Steenland et al., 2022) providing evidence that effects detectable at low exposures are concordant with effects seen in high-exposure studies. These studies are discussed in the draft and final toxicity assessments (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). Additionally, in a relatively recent review, Steenland et al. (2020) discussed the probable link between kidney cancer and PFOA exposure following the assessments of the C8 Science Panel. The exclusion of these studies indicate that the commenter has cherry-picked from the available evidence to support their narrative. Importantly and in accordance with the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a), the EPA considers the full weight of evidence approach when characterizing hazard.

The commenter raised several concerns about the Shearer et al. (2021) study. First, the commenter incorrectly stated that use of Shearer et al. (2021) for POD derivation is undermined by the study's reliance on PFOA exposure measured at a single point in time almost a decade before cancer diagnosis. However, the EPA determined that the biomonitoring measures of PFOA levels in Shearer et al. (2021) were reliable measures of PFOA exposure due to the chemical's well-established long half-life (see Section 3.3 of the final toxicity assessment for PFOA (USEPA, 2024d)). As a result, PFOA levels in serum remain relatively stable over long periods of time (i.e., years). Additionally, adequate study of cancer outcomes requires consideration of the latency period of the disease. Cancer is generally not an acute outcome that develops immediately following chemical exposures (USEPA, 2005). The study's measurement of PFOA one decade prior to diagnoses was appropriate considering the nature of the outcome of interest.

The commenter misleadingly asserted that Shearer et al. (2021) insufficiently adjusted for "key risk factors," mentioning limited categorical analyses of smoking history, body mass index (BMI), and history of hypertension. However, this case-control study also used matching techniques (i.e., matched characteristics between cases and controls) to account for a number of additional confounders including age, sex, race/ethnicity, study center, and study year of blood

draw. Matching is a well-established and appropriate method of accounting for key confounders in case-control studies. As mentioned in a previous response, the EPA considered the author's approach to investigating, evaluating, and addressing confounding in this study to be adequate. The EPA also notes that the guidance referred to by the commenter (USEPA, 2005) clearly suggests "examples" of covariates to be considered and does not provide a "necessary and sufficient" list of covariates that need be included in an epidemiological study. Such a prescribed method would be inappropriate given the enormous breadth of epidemiological study designs, considerations of varying populations, exposure and outcomes, appropriate adjustment for and evaluation of potential confounders, and considerations of overadjustment bias.

Regarding the comment on "modest" PFOA levels in the Shearer (2021) study, the commenters referenced results that found no significant associations between PFOA and kidney cancer in an exposed study population from a *low* confidence study (Raleigh et al., 2014). However, Raleigh et al. (2014) presented results from an occupationally exposed population with different exposure patterns than those typically found in the general population, and the lack of association in this high exposure setting does not discredit associations found in other studies. Therefore, the EPA disagrees with the commenter's statement that this "should have been considered by EPA as strong evidence against carcinogenicity." In fact, associations found at lower levels of exposures, such as in Shearer et al. (2021), which are based on or are relevant to exposure levels in the general U.S. population, indicate that the general population is at risk. Additionally, Raleigh et al. (2014) was rated as *low* confidence and would not serve to discredit the results found in a study of higher confidence, such as Shearer et al. (2021). Raleigh et al. (2014) used modeled estimates of PFOA air concentrations in the workplace rather than biomonitoring measurements. This is a concern because the study lacks information about the degree to which inhaled PFOA is absorbed in humans and factors that may affect absorption. Additionally, PFOA exposure data in non-production workers was not based on actual measurements. Possible reasons that this study failed to identify the association between PFOA exposure and kidney cancer include relatively small numbers of cases, lack of information on adjustment for risk factors of kidney cancer such as smoking status and BMI, and the methods for exposure assessment. Finally, Raleigh et al. (2014) noted that their study had limited power to evaluate some cancers, and that case ascertainment from one study population was likely incomplete.

The commenter asserted that "the distribution of 81 controls and only 47 cases in the referent group is counterintuitive," it "may have biased the statistical comparisons for the other exposure categories," and it "becomes the main driver in the subsequent calculations for the other three exposure categories." However, the commenter did not substantiate these assertions with factual evidence or references. In contrast, the EPA concluded that the Shearer et al. (2021) study adequately defined the categories of PFOA based on the quartiles of serum PFOA *in the controls* which is best practice in analyses of case-control data (Breslow and Day, 1984; Velarde et al., 2022). Thus, it is unclear to the EPA what is "counterintuitive" about the particular case-control numbers in the reference group. The EPA also notes that there was evidence of an effect in the analysis of serum PFOA as a continuous variable (log2 transformed), thus rendering the commenter's assertion of "bias" unsubstantiated by the facts.

Finally, the commenter suggests that PFOA "is more likely to act via a threshold mode of action." In Section 3.5.4 of the final toxicity assessment for PFOA (USEPA, 2024d), the EPA determined "[t]he available data is limited in its ability to provide enough evidence to support conclusions about potential MOAs for PFOA-induced kidney and testicular tumors in humans. Similarly, there is limited data to support specific MOAs for PFOA-induced testicular and pancreatic tumors in rats… the available *in vivo* and *in vitro* assays provide considerable support that PFOA may induce tumorigenesis through multiple mechanisms that are considered key characteristics of carcinogens." The EPA provided discussion on the human relevance of tumors observed in animal models, noting that there is uncertainty associated with some of the potential MOAs, such as PPARα, but others should be considered relevant to humans (e.g., cytotoxicity, testosterone biosynthesis inhibition). Additionally, the EPA reiterates that tumors have been reported in human populations, clearly in contrast to claims that PFOA acts through MOAs that are entirely irrelevant to human biology. In combination, there is a lack of evidence to support a threshold (i.e., nonlinear) MOA for PFOA. To determine this, the EPA conducted a weight of evidence analysis and followed the MOA framework outlined in the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005), in contrast to the commenters claims that the agency relied on default assumptions rather than conducting an evidence-based analysis (available in Section 3.5.4; USEPA, 2024d). As stated in the *Guidelines*, "[n]onlinear approaches generally should not be used in cases where the mode of action has not been ascertained," as is the case for PFOA (USEPA, 2005).

While the commenter was correct in stating that the majority of the available literature that evaluates the potential mutagenicity of PFOA is negative, mutagenicity is not the only the determinant of whether a chemical acts through a nonlinear MOA. The commenter was incorrect in stating that a lack of evidence supporting mutagenicity results in the EPA identifying a dose below which toxicity does not occur and setting the MCLG based on that dose (i.e., the nonlinear dose-response approach). In fact, the *Guidelines* explicitly state two criteria that must be met for a nonlinear approach to be selected for dose-response analyses: "when there are sufficient data to ascertain the mode of action and conclude that it is not linear at low doses and the agent does not demonstrate mutagenic or other activity consistent with linearity at low doses" (USEPA, 2005). As described above, the EPA did not identify sufficient evidence supporting a nonlinear MOA and the commenter additionally did not provide literature to support this assertion. Therefore, the EPA maintains its position that there is insufficient evidence to support a nonlinear MOA for PFOA and the MCLG should be set at zero.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053422)

For the PFOA cancer classification, EPA bases the determination "on the evidence of kidney and testicular cancer in humans and LCTs, PACTs, and hepatocellular adenomas in rats."[FN132: See EPA Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) (CASRN 335-67-1) in Drinking Water at page 3-306.] EPA is clear that "there is not convincing epidemiological evidence supporting a causal association between human exposure to PFOA and cancer," and notes state that "there is significant

uncertainty regarding the carcinogenic MOA(s) of PFOA, particularly for renal cell carcinomas and testicular cancer in humans" (emphasis added) [FN133: Id. At 6-8 to 6-9.]. The epidemiological literature is very inconsistent, particularly for kidney cancer,[FN134: See comments submitted by Nessa Horewitch Coppinger on behalf of the 3M Company, Feb. 10, 2022, at page 13, available at: https://sab.epa.gov/ords/sab/f?p=100:19:16404771425364:::RP,19:P19_ID:963.] yet EPA relies on the Shearer et al. 2021 study, which did not show statistically significant increases in kidney cancer after adjusting for other PFAS, to justify the "likely to be carcinogenic" classification. In its review, the SAB stated that EPA's rationale for the cancer designation was "not adequately provided" and that additional "weight of evidence" narrative was needed [FN135: See SAB report to the EPA Administrator Aug 22, 2022, at pages 32-33, available at: https://sab.epa.gov/ords/sab/f?p=100:18:16490947993:::RP,18:P18_ID:2601#report.]. Now that EPA has provided a new framework and justification, an additional SAB review is warranted. Without external peer review, stakeholders will not have the level of confidence that SDWA typically provides through the rigorous requirement for peer review. If more fulsome and complete documents had been provided to the SAB to inform its review, then additional peer review would not now be required.

EPA Response: Regarding comments on the evidence supporting the EPA's cancer classification for PFOA, please see section 4.1.4 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683in section 4.1.4.3 in this *Response to Comments* document. More specifically, the EPA followed agency guidance when determining the cancer descriptor for PFOA, which does not state that there must be evidence from epidemiological studies demonstrating causal associations between exposure and cancer risk or known MOAs for determinations that a contaminant is *Likely to be Carcinogenic to Humans* (USEPA, 2005). Regarding comments on the peer-review process for this rulemaking, please see section 4.1.3 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-044827)

EPA Cannot Conclude that PFOA and PFOS are Likely to be Carcinogenic to Humans and Its Cancer Slope Factor Derivations are Flawed

EPA proposes to set the MCL Goal at zero for PFOA and PFOS based on the conclusion that both are likely to be carcinogenic to humans. As a consequence, and consistent with the Safe Drinking Water Act (SDWA), EPA proposes to set the enforceable MCL as close to the Goal as is determined to be feasible. In the case of PFOA, EPA's conclusion is based on elevated levels of kidney cancer (renal cell carcinoma, or RCC) reported by Shearer et al. (2021). [FN5: Shearer JJ et al. Serum concentrations of per-and polyfluoroalkyl substances and risk of renal cell carcinoma. J Natl Cancer Inst 113:580-587 (2021).] However, this finding is not supported by the results from other studies where the potential for exposure to PFOA was better characterized.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683in section 4.1.4.3 in this *Response to Comments* document. Similar to the EPA's response to this commenter's assertion about PFOS (comment Doc. #1841, SBC-044830), the EPA also disagrees that the cancer assessment conclusions resulted in an overly conservative MCLG for PFOA.

American Chemistry Council (ACC) (Doc. #1841, SBC-053414)

The determination of the potential carcinogenicity of PFOA relies on an epidemiology study that determines exposure based on a single blood sample, despite the existence of other, conflicting studies based on a more robust exposure assessment.

EPA Response: Please see section 4.1.4 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683 in section 4.1.4.3 in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-052923)

The Available Animal Evidence Does Not Support a Conclusion that PFOA is a Likely Carcinogen at Low Doses

Considering the uncertainty in the epidemiological database, it is important to look at the results of cancer studies in laboratory animals for biological plausibility and concordance with findings in humans. While several bioassays have been conducted, none have reported an increase in kidney cancer among the exposed animals. Reported cancers have included liver, pancreas, and Leydig cell (LC) cancers. The most recent of these studies was conducted by the National Toxicology Program (NTP). [FN24: NTP. Technical report on the toxicology and carcinogenesis studies of perfluorooctanoic acid administered in feed to Sprague-Dawley rats. Technical Report 598. Department of Health and Human Services. Research Triangle Park, North Carolina (2019). (NTP PFOA Bioassay Technical Report)] In addition, no plausible biological basis for the development of tumors from PFOA exposure has been reported. Without it, there does not appear to be sufficient information to establish causation.

A significant amount of genotoxicity and mechanistic data on PFOA is available to assist in evaluating the results of the epidemiology and animal bioassay results described above. Multiple in vivo and in vitro assays provide clear evidence that PFOA is not mutagenic and may only cause genotoxicity at cytotoxic concentrations. Consequently, it is generally agreed that PFOA causes tumors in laboratory animals via a non-genotoxic or epigenetic mechanism. [FN25: USEPA. Health Effects Support Document for Perfluorooctanoic Acid (PFOA). EPA 822-R-16-003. Office of Water. Washington, DC. (May 2016). (USEPA PFOA HESD 2016)]

The tumor types that have been reported consistently in rats exposed to PFOA – liver, LC, and pancreatic acinar cell (PAC) – have been observed with other substances that are peroxisome

proliferator-activated receptor alpha (PPARα) agonists. Because of key toxicodynamic and biological differences in responses between rodents and humans, PPARα activators are considered unlikely to induce tumors in humans. For liver tumors, this conclusion is based on minimal or no effects observed on growth pathways, hepatocellular proliferation and liver tumors in humans and/or species (e.g., Cynomolgous monkeys) that are more appropriate animal model surrogates than mice and rats. Several key studies provide support for the key events (Kes) in the proposed PPARα-activated mode of action (MOA) for rat liver tumors. These data are summarized by Klaunig et al. (2012) –

Analysis of gene expression changes elicited following short-term administration of PFOA demonstrated the up regulation of genes characteristic of PPARα activation, including genes involved in fatty acid homeostasis/peroxisomal proliferation as well as those related to cell cycle. In addition, PFOA has been shown to induce peroxisome proliferation in mouse and rat liver and causes hepatomegaly in mice and rats. While the liver growth caused by PFOA was predominantly attributed to a hypertrophic response, an increase in DNA synthesis following PFOA exposure was observed and predominated in the periportal regions of the liver lobule. Thus, the effect of PFOA on induction of cell cycle gene expression and the increase in DNA synthesis provide evidence in support of both [KE] 2 and 3 in the proposed MOA for liver tumor induction by PFOA. Empirical evidence also exists in support of the clonal expansion of preneoplastic hepatic lesions by PPARα activators (Step 4). Using an initiation-promotion protocol for induction of liver tumors in Wistar rats, PFOA was shown to increase the incidence of hepatocellular carcinomas in rat liver (33% in PFOA exposed rats vs. 0% in controls). [FN26: Klaunig JE et al. Mode of action analysis of perfluorooctanoic acid (PFOA) tumorigenicity and human relevance. Reprod Toxicol 33:410-418 (2012).]

EPA Response: The commenter stated that the evidence related to the carcinogenicity of PFOA does not support a designation of *Likely to Be Carcinogenic to Humans*. The EPA disagrees with the explanations provided by the commenter to support this claim. Comments regarding the epidemiological evidence for the carcinogenic potential of PFOA, the lack of kidney cancer incidence observed in the available animal toxicological studies, the "biological basis" (i.e., proposed MOA) for tumor development, the use of genotoxicity data to support cancer assessments and classifications, and the human relevance of various tumor types resulting from PFOA administration are discussed in section 4.1.4 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683 in section 4.1.4.3 in this *Response to Comments* document. The commenter does not provide supporting evidence for their claims that was not already considered and cited by the EPA in the agency's toxicity assessment of PFOA and in the PFOA and PFOS MCLG technical support document (USEPA, 2024d; USEPA, 2024e).

AWWA (Doc. #1759, SBC-045597)

According to the proposal, EPA is proposing an MCLG of 0 ppt (zero) for PFOA based on a determination that PFOA is likely to be carcinogenic. AWWA has previously reviewed the EPA's

determination that PFOA is carcinogenic and provided comments (AWWA, 2021a). Key aspects of those comments are shown below and can be found in more detail in Appendix A.

1. EPA cites Shearer et al (2021) as a key study showing that PFOA may be carcinogenic. This study may not be suitable as evidence to support this determination given that the study duration spanned less than 18 years. Given the half-life of PFOA, it is unlikely to accurately portray the exposure relevant to the development of kidney cancer.

2. In epidemiological studies of higher exposures there has been inconsistent evidence of increased cases of kidney cancer. For example, epidemiological studies of residents exposed to PFOA and other PFAS in contaminated drinking water have reported modest increases whereas occupational cohorts have shown increased and decreased risk of kidney disease, despite higher exposure and longer study durations.

If EPA moves forward with a conclusion that PFOA is carcinogenic, AWWA agrees that the appropriate MCLG for a carcinogen is 0 ppt (zero).

EPA Response: The commenter reiterated to two specific points that were initially described by the commenter in a document sent to the SAB for its consideration at the time of peer review regarding the EPA's use of Shearer et al. (2021) to support the cancer classification for PFOA and their perceived inconsistencies in the epidemiological database for kidney cancer and disease. Responses for these comments are available in section 4.1.4 of the EPA response in this *Response to Comments* document and in the EPA response to comment Doc. #1774, SBC-045682 and SBC-045683 in section 4.1.4.3 in this *Response to Comments* document. More specifically, the biomonitoring measures of PFOA levels in Shearer et al. (2021) were reliable measures of PFOA exposure due to the chemical's well-established long half-life (see Section 3.3 of USEPA (2024a)). As a result, PFOA levels in serum remain relatively stable over long periods of time (i.e., years). The commenter incorrectly states that the "study duration [of Shearer et al. (2021)] spanned less than 18 years." In fact, the Shearer et al. (2021) study reported that diagnoses of renal cell carcinoma occurred between 2-18 years after the pre-diagnostic serum samples were collected. Since the study reported diagnosed cases of RCC, it therefore had adequate study sensitivity (i.e., a follow-up period of 18 years or less adequately captured RCC incidence). Additionally, the study duration for epidemiological studies is not the same as the exposure duration; patients included in Shearer et al (2021) were likely exposed to PFOA and other PFAS throughout their lifetimes and were aged 55 years and older, which is an adequate exposure duration considering the latency of cancer as the outcome of interest (USEPA, 2005).

Regarding kidney disease, the EPA concluded the epidemiological evidence for renal health outcomes was slight, which was based on "evidence of decreased kidney function among children and adults, including increased uric acid and hyperuricemia and decreased eGFR," but there were uncertainties related to mixed results, study quality, and potential reverse causality (USEPA, 2024d, Appendix C.5). A lack of evidence reporting associations between PFOA exposure and kidney disease does not detract from epidemiological evidence of positive associations between PFOA exposure and kidney cancer.

The commenter additionally points the EPA to comments they present in Appendix A of their submission. Responses to those comments are available in sections 4.2 and 13 of the EPA response in this *Response to Comments* document, depending on the topic described.

The commenter supported the EPA setting an MCLG of zero if the EPA maintains the conclusion that PFOA is *Likely to Be Carcinogenic to Humans*. The EPA agrees with this statement.

4.1.5 The EPA's Proposed MCLGs of Zero for PFOA and PFOS

Summary of Major Public Comments and EPA Responses

Many commenters supported the EPA's proposed MCLGs of zero for both PFOA and PFOS, citing well-documented health effects, including cancer, resulting from exposure to either PFOA or PFOS as rationale for their support of the proposed rulemaking. Several commenters also agreed with the EPA's long-standing practice of establishing the MCLG at zero (see USEPA, 1998; USEPA, 2000a; USEPA, 2001; *See* S. Rep. No. 169, 104th Cong., 1st Sess. (1995) at 3) for known or likely linear carcinogenic contaminants, with one commenter stating that it is "appropriate based on the weight of evidence for carcinogenicity and other adverse health impacts of PFOA and PFOS at very low exposures."

Two commenters disagreed with MCLGs of zero for PFOA and PFOS, with one commenter claiming that the EPA's determinations were "not consistent with the evidence the EPA presents nor with its own guidance" (i.e., the EPA's cancer assessment was not consistent with assessment approaches recommended in the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005)).

To establish an MCLG for individual contaminants, the EPA assesses the peer-reviewed science examining cancer and noncancer health effects associated with oral exposure to the contaminant. For nonlinear carcinogenic contaminants, contaminants that are designated as *Suggestive Human Carcinogens* (USEPA, 2005), and non-carcinogenic contaminants, the EPA typically establishes the MCLG based on a noncancer RfD. An RfD is an estimate of a daily oral exposure to the human population (including sensitive populations) that is likely to be without an appreciable risk of deleterious effects during a lifetime. A nonlinear carcinogen is a chemical agent for which the associated cancer response does not increase in direct proportion to the exposure level and for which there is scientific evidence demonstrating a threshold level of exposure below which there is no appreciable cancer risk. For known or likely linear carcinogenic contaminants, where there is a proportional relationship between dose and carcinogenicity at low concentrations or where there is insufficient information to determine that a carcinogen has a threshold dose below which no carcinogenic effects have been observed, the EPA has a long-standing practice of establishing the MCLG at zero (see USEPA, 1998; USEPA, 2000a; USEPA, 2001; *See* S. Rep. No. 169, 104th Cong., 1st Sess. (1995) at 3). Section 1412(b)(4)(A) requires that the MCLG "be set at the level at which no known or anticipated adverse effects on the health of persons occur and which allows for an adequate margin of safety." The MCLG "incorporates a margin of safety to reflect scientific uncertainty and, in some cases, the particular susceptibility of some groups

(e.g., children) within the general population" (S. Rep. No. 169, 104th Cong., 1st Sess. (1995) at 3).The EPA's general practice and decision here to set the MCLGs for PFOA and PFOS at zero based on information presented in the record (USEPA, 2024d; USEPA, 2024c; USEPA, 2024e) ensures that the MCLG is set at a level of "no known or anticipated adverse effects on the health of persons occur" and also "allows for an adequate margin of safety", which is intended to reflect scientific uncertainty and also "allows for an adequate margin of safety." This level (0 ppt) both ensures that the statutory criterion is met, in light of and accounting for scientific uncertainty, and protects all populations, including vulnerable populations identified in the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c).

The EPA disagrees with commenters' assertions because there is sufficient evidence for carcinogenicity of both PFOA or PFOS exposures supporting classifications of *Likely to Be Carcinogenic to Humans* according to the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) from the available epidemiological and animal toxicological studies. Consistent with the guidelines, the EPA provided a narrative to "explain the case for choosing one descriptor and discuss the arguments for considering but not choosing another" (USEPA, 2005) in the draft and final toxicity assessments (USEPA, 2024d; USEPA, 2024c; USEPA, 2023f; USEPA, 2023a). Please see also section 4.1.4 of the EPA response in this *Response to Comments* document.

Individual Public Comments

Petersburgh C8 (PFAS) Committee (Doc. #2714, SBC-047422)

To The EPA:

The amount of any PFAS/PFOS compound that we should be exposed to is zero. We live near Taconic Plastics, a SuperFund Site in Petersburgh, NY. This industry has released these toxins into our aquifer, our town water supply, our private wells, our soil, our air, and most likely our food that we grow in this rural area during the last 50 years.

We know that the long chain compounds previously used - and still in our water supply - are extremely toxic. We know that the factory is now using short chain compounds, though they won't tell us which ones; we know that these have also been proven to be toxic. We smell the emissions almost daily and have discovered that air deposition has contributed to water contamination in our community as well as others nearby. Since the information is proprietary, we have no idea of the compounds they are using and releasing.

EPA Response: The comments provided by this commenter support the final rule.

Natural Resources Defense Council (Doc. #3072-6, SBC-053424)

Appropriately, EPA has proposed MCLGs of zero and MCLs of 4 parts per trillion for PFOA and PFOS, limits that are both scientifically supported and technologically available with currently available water treatment systems.

EPA Response: The comments provided by this commenter support the final rule.

Joe DiNardo (Doc. #1725, SBC-045756)

EPA Proposed National Primary Drinking Water Regulation (NPDWR)
Comme//www.regulations.gov/document/EPA-HQ-OW-2022-0114-0027)

Joe DiNardo – Personal Care Products Toxicologist since 1976

I would first like to thank the EPA for their tremendous efforts and advances made in establishing guidelines to control the human and environmental impact of Per- and Polyfluoroalkyl Substances (PFAS). With that said, I respectfully submit the following comments for EPA's review and consideration in light of the proposed National Primary Drinking Water Regulation (NPDWR):

1) EPA Statement:

"Following a systematic review of available human epidemiological and animal toxicity studies, EPA has determined that PFOA and PFOS are likely to cause cancer (e.g.,kidney and liver cancer) and that there is no dose below which either chemical is considered safe (see section IV.A and V.A through B of this preamble for additional discussion). Therefore, EPA is proposing to set the health-based value, the MCLG, for both of these contaminants at zero."

I agree with EPA's safety assessment that PFOA and PFOS are likely carcinogenic to humans and with the conclusion that there is no dose that is safe and, therefore, setting an MCLG to "Zero" is logical.

EPA Response: The comments provided by this commenter support the final rule.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-044019)

EPA requests comment on the derivation of the proposed MCLG for PFOA and its determination that PFOA is Likely to be Carcinogenic to Humans and whether the proposed MCLG is set at the level at which there are no adverse effects to the health of persons and which provides an adequate margin of safety.

a. It is standard for (potential) carcinogens to have an MCLG of zero.

EPA Response: The comments provided by this commenter support the final rule.

Suffolk County Water Authority (SCWA) (Doc. #1589, SBC - 043365)

Establishment of Maximum of Contaminant Level Goals Provides an Important Benchmark for Public Water Suppliers

SCWA bylaws provide that the SCWA's mission is to serve its customers "the highest quality water at the lowest possible cost with excellent customer service." Serving the highest quality

water means that the SCWA's mission is to treat water to the maximum contaminant level goal (MCLG) whenever feasible because that is the level at which there is no known or anticipated effects on the health of persons.

When the State of New York adopted MCLs for PFOA and PFOS, it did not adopt any MCLGs. Like 24 other states, New York does not currently utilize MCLGs as part of its public health law or its state sanitary code. Based upon SCWA's review of the regulatory record of the New York State Department of Health for PFOA and PFOS, it appeared that the MCLG for both contaminants would be zero if New York utilized MCLGs because they are likely human carcinogens, and there was insufficient information to determine if there was a threshold dose below which there were no carcinogenic effects. The EPA's proposal to establish MCLGs of zero for PFOA and PFOS provides confirmatory guidance to the SCWA regarding this important benchmark. [SB1] [EM2]

EPA Response: The comments provided by this commenter support the final rule.

Citizens Campaign for the Environment (CCE) (Doc. #1710, SBC-045131)

• Adopt the MCL Goal of zero for PFOA and PFOS

As suspected carcinogens, there is no safe level of exposure to these harmful PFAS chemicals. EPA's recent update of its health advisory for PFOS and PFOA has made clear that there is essentially no safe level of exposure to these chemicals in drinking water. CCE supports setting MCLG's at zero for a number of important reasons, including:

• Vulnerable populations, including infants, the elderly, and those with compromised immune systems may choose to only consume water that presents no known or anticipated adverse health effects.

EPA Response: This commenter supports the conclusions of the EPA's proposed rule and specifically highlighted the protection of vulnerable populations as rationale for adopting the MCLGs of zero. The EPA is issuing a final rule consistent with this comment; please also see section 4.1.5 of the EPA response in this *Response to Comments* document.

Kevin Korro (Doc. #1538, SBC-042654)

Individual Maximum Contaminant Levels (MCLs) for PFOA and PFOS were established at 4.0 nanograms per liter (ng/L) or parts per trillion (ppt), while the proposed Maximum Contaminant Level Goals (MCLGs) for PFOA and PFOS were set at zero. These are goals that have my complete support.

EPA Response: The comments provided by this commenter support the final rule.

A. O. Smith Corporation (Doc. #1674, SBC-043691)

Maximum Contaminant Level Goal

A. O. Smith supports the EPA's MCLG determinations for the six identified PFAS compounds and agrees that these chemicals are likely to create adverse health impacts in human beings at high exposure levels. Therefore, a goal of removing them from the nation's drinking water supply is appropriate.

EPA Response: The comments provided by this commenter support the final rule.

New Jersey Department of Environmental Protection (NJDEP) (Doc. #1699, SBC-045017)

NJDEP also agrees that the proposed MCLGs of zero for PFOA and PFOS are consistent with the approach used by EPA since the 1980s for setting MCLGs for Category I contaminants (i.e., known and likely human carcinogens under the USEPA [2005] Cancer Risk Assessment Guidelines; Groups A, B1, and B2 under the earlier USEPA [1986, 1999] guidelines), as described on p. 186530 of the proposed rule. According to the USEPA (2005) cancer risk assessment guidelines, any level of exposure to a known or likely carcinogen is assumed to cause some risk of cancer unless a threshold mode of action has been demonstrated. As such, EPA sets MCLGs for known and likely human carcinogens at zero to ensure that "there are no anticipated adverse health effects with a margin of safety" unless a threshold for carcinogenicity has been established. Since a threshold mode of action for carcinogenicity has not been established for PFOA and PFOS, it is appropriate that the MCLGs for these two PFAS are set at zero.

EPA Response: The comments provided by this commenter support the final rule. Specifically, the commenter agreed with the proposed MCLGs of zero, stating that this approach is consistent with past precedent and conclusions regarding the carcinogenicity and MOAs of PFOA and PFOS. The EPA agrees with the commenter's conclusions.

3M Company (Doc. #1774, SBC-053427)

Further, EPA reliance on cancer endpoints as the basis for a maximum contaminant level goal (MCLG) of zero for PFOA and PFOS is not consistent with the evidence EPA presents nor with its own guidance.

EPA Response: The EPA disagrees with this comment. Please see sections 4.1.5 and 4.1.4 of the EPA response in this *Response to Comments* document regarding the EPA's determination that PFOA and PFOS are *Likely to Be Carcinogenic to Humans* (USEPA, 2005).

American Chemistry Council (ACC) (Doc. #1711, SBC-044458)

The Agency's proposal suffers from the following significant shortcomings –

The proposal to establish maximum contaminant level (MCL) goals of zero for both PFOA and PFOS is not consistent with the available cancer weight of scientific evidence for the substances.

EPA Response: The EPA disagrees with this comment. Please see sections 4.1.5 and 4.1.4 of the EPA response in this *Response to Comments* document regarding the EPA's determination that PFOA and PFOS are *Likely to Be Carcinogenic to Humans* (USEPA, 2005).

American Chemistry Council (ACC) (Doc. #1841, SBC-044816)

The Agency's proposal would establish MCL Goals for PFOA and PFOS of zero based on a conclusion that they are likely human carcinogens under the Agency's Cancer Risk Guidelines [FN3: USEPA. Guidelines for Cancer Risk Assessment. EPA/630/P-03/001F. Risk Assessment Forum (2005). (USEPA Cancer Risk Guidelines)] and a combined MCL Goal for PFBS, HFPO-DA, PFHxS, and PFNA based on a novel and unprecedented hazard index (HI) approach. While EPA proposes to set the enforceable MCL for the HI of the four substances at the MCL Goal, the MCL for PFOA and PFOS would be set at the minimum reporting level determined by the Agency for each substance. In support of its proposal, EPA has developed estimates of the costs of complying with the proposed standards and the expected benefits in public health that it predicts will be achieved as a result of the standards.

As outlined in these comments, the Agency's proposal suffers from a number of significant shortcomings, including the following –

The proposal to establish maximum contaminant level (MCL) goals of zero for both PFOA and PFOS is not consistent with the available cancer weight of scientific evidence for the substances.

EPA Response: The EPA disagrees with these comments. Please see sections 4.1.5 and 4.1.4 of the EPA response in this *Response to Comments* document regarding the EPA's determination that PFOA and PFOS are *Likely to Be Carcinogenic to Humans* (USEPA, 2005). Regarding the Hazard Index MCLG, please see section 4.3 of the EPA response in this *Response to Comments* document. Regarding the MCLs, please see section 5 of the EPA response in this *Response to Comments* document. Regarding the estimated benefits and costs, please see section 13 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-044779)

May 15, 2023

The Honorable Michael S. Regan

Administrator

US Environmental Protection Agency

1200 Pennsylvania Avenue

Washington, DC 20460

Re: PFAS National Drinking Water Regulation Rulemaking; Preliminary Regulatory Determination and Proposed Rule, 88 Federal Register 18638 (March 29, 2023), EPA- HQ-OW-2022-0114

Dear Administrator Regan:

The American Chemistry Council (ACC) submits the enclosed comments on the preliminary regulatory determination for four per- and polyfluoroalkyl substances (PFAS) under the Safe Drinking Water Act (SDWA) and the proposal to establish national primary drinking water standards for these four substances, perfluorooctanoate (PFOA), and perfluorooctane sulfonate (PFOS) under the Act. The Agency's proposal suffers from the following significant shortcomings –

The proposal to establish maximum contaminant level (MCL) goals of zero for both PFOA and PFOS is not consistent with the available cancer weight of scientific evidence for the substances.

EPA Response: The EPA disagrees with this comment. Please see sections 4.1.5 and 4.1.4 of the EPA response in this *Response to Comments* document regarding the EPA's determination that PFOA and PFOS are *Likely to Be Carcinogenic to Humans* (USEPA, 2005). Regarding the regulatory determinations for four additional PFAS substances, please see section 3 of the EPA response in this *Response to Comments* document.

4.2 The EPA's Toxicity Assessments for PFOA and PFOS

Summary of Major Public Comments

The EPA requested comments on different aspects of the draft toxicity assessments of PFOA and PFOS. The EPA received comments on a variety of topic areas that fall outside the scope of the MCLG derivation, including comments on the noncancer health outcome conclusions, toxicity value derivations, relative source contribution (RSC), the pharmacokinetic modeling approach, non-prioritized health outcomes (e.g., endocrine), and others. Some commenters requested clarification on the information presented in the draft toxicity assessments. The EPA's responses to these issues as well as others expressed by individual commenters are described in further detail below.

4.2.1 The EPA's Conclusions on Noncancer Health Outcomes

Summary of Major Public Comments and EPA Responses

The EPA requested comment on its assessment of the noncancer effects associated with exposure to PFOA and PFOS. Some commenters supported and some commenters criticized the EPA's conclusions regarding noncancer health effects associated with PFOA and PFOS exposure.

Several commenters highlighted the multitude of adverse noncancer health outcomes that are associated with PFOA or PFOS exposure and the large volume of literature providing evidence supporting the regulation of these compounds. A few commenters specifically expressed support

for one or more of the four priority noncancer health outcomes (i.e., developmental, immune, hepatic, and cardiovascular) identified by the EPA in the toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). These commenters are also in agreement with the SAB PFAS Review Panel, who stated, "[m]ultiple studies for each of these four effects are generally consistent in different populations and settings, and the total body of evidence indicates that these effects are present" (USEPA, 2022b).

A few commenters disagreed with the EPA's conclusions regarding the selection of four noncancer health outcomes prioritized in the PFOA and PFOS toxicity assessments. A few commenters stated that the human epidemiological evidence for one or more of the priority health outcomes was too inconsistent to support the EPA's strength of evidence determinations. A few commenters claimed that flaws in the EPA's approach (e.g., inconsistent study evaluations, selective consideration of epidemiological studies, improper evidence integration) resulted in the agency drawing incorrect conclusions regarding the strength of evidence for these noncancer health outcomes. A few commenters stated that they disagreed because the research is still ongoing and there is limited evidence for associations between PFOA or PFOS and adverse health effects in humans.

The EPA disagrees with the claim that the effects observed in the epidemiological databases for the four priority noncancer health outcomes are inconsistent. The EPA documented the weight of evidence in evidence profile tables, which organize and integrate evidence across the epidemiological, animal toxicological, and mechanistic data (see Section 3 of USEPA (2024d) and USEPA (2024c)) consistent with the ORD IRIS Handbook (USEPA, 2022a). This documentation is detailed, transparent, and clear. The epidemiological databases for each health outcome were determined to have moderate evidence of an association between PFOA or PFOS and the outcome of interest. This means that the evidence across studies supports a conclusion that the effect(s) results from the exposure being assessed (i.e., PFOA or PFOS) with only some uncertainty due to potential chance, bias, or confounding (USEPA, 2022a). More specifically, each critical effect was represented by multiple epidemiological studies of high and/or medium confidence that showed consistent direction of effect in the target population(s) and, importantly, coherence with evidence presented in animal toxicological studies. These factors, combined with the EPA's practice that "human data are preferred over animal data to eliminate interspecies extrapolation uncertainties" (USEPA, 2022a), support the EPA's decision to use human epidemiological studies for quantitative analyses.

As described in section IV of the Federal Register Notice, the EPA disagrees with commenters' claims that there were flaws in the assessment approach that resulted in the mischaracterization of hazards associated with PFOA and PFOS exposure. The EPA followed the state-of-the-art systematic review best practices from the ORD Staff Handbook for Developing IRIS Assessments (USEPA, 2022a) and the *Systematic Review Protocol for the PFBA, PFHxA, PFHxS, PFNA, and PFDA (anionic and acid forms) IRIS Assessments* (USEPA, 2021a) when developing the protocol used as the basis for study quality evaluations, evidence integration, and critical study selection, and followed other agency guidance as applicable. Additionally, the SAB

provided many recommendations to further strengthen the EPA's protocol and the EPA fully addressed the SAB PFAS panel's recommendations (USEPA, 2023d), resulting in scientifically sound toxicity assessments (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). Importantly, the SAB PFAS Panel "…agreed with many of the conclusions presented in the assessments," including the EPA's focus on "health outcomes that have been concluded to have the strongest evidence, including the liver disease, immune system dysfunction, serum lipid aberration, impaired fetal growth, and cancer" (USEPA, 2022b).

While the EPA acknowledges that there is ongoing health effects research for PFOA, PFOS, and PFAS as a class, the EPA disagrees with the characterization that there is limited evidence to support the findings and conclusions of this rulemaking. In fact, there is a substantial amount of evidence supporting the EPA's hazard characterizations for PFOA and PFOS as reflected in the Interactive Flow Diagram developed by the EPA to visualize the available literature in section 3.1 of the toxicity assessments (availablublic.tableau.com/app/profile/pfoapfos2023/viz/InteractiveReferenceFlowDiagramforPFOAPFOS_16615197966440/PFOAPRISMADiagram); there are hundreds of *medium* and *high* confidence published studies describing associations between PFOA and/or PFOS and adverse health effects. The strength of evidence supporting these association are summarized in the evidence profile tables found in sections 3.4.1.4 (hepatic), 3.4.2.4 (immune), 3.4.3.4 (cardiovascular), and 3.4.4.4 (developmental) of the toxicity assessments (USEPA, 2024d; USEPA, 2024c). Additionally, the studies identified in the final supplemental literature search conducted in February 2023 continue to support the conclusions of the toxicity assessments for PFOA and PFOS (USEPA, 2024a; USEPA, 2024b; Appendix A3).

Based on the results of the literature searches conducted through 2022, there was evidence of increases in total cholesterol (TC) concentrations (19/23 studies) associated with elevated exposure to PFOA in studies of adults (see Section 3.4.3 of USEPA, 2024d). Similarly, there was evidence of increases in TC concentrations (18/23 studies) associated with elevated exposure to PFOS in studies of adults (see Section 3.4.3 of USEPA, 2024c). Consistency for increases in TC concentrations in adults associated with elevated exposure to PFOA and PFOS was supported by additional studies identified from the EPA's supplemental literature search in 2023. Specifically, for PFOA, 10 out of 11) studies evaluating changes in TC reported increases in TC with elevated exposure to PFOA and 6 out of 11 reported statistically significant increases (Section A.3 of USEPA, 2024a). Similarly, for PFOS, 10 out of 11 studies evaluating changes in TC reported increases in TC with elevated exposure to PFOS and 8 out of those 11 reported statistically significant changes in TC (Section A.3 of USEPA, 2024b). Together, these studies support the EPA's conclusion that the evidence indicates elevated exposures to PFOA or PFOS are associated with adverse cardiovascular effects, specifically serum lipids, as well as EPA's selection of increased total cholesterol in adults for dose-response modeling.

Based on the results of the literature searches conducted through 2022, there were 30 studies reporting deficits in BWT (30/42) associated with elevated exposure to PFOA (see Section 3.4.4 of USEPA, 2024d). Similarly, there were 27 studies reporting deficits in BWT (27/39) associated

with elevated exposure to PFOS (see Section 3.4.3 of USEPA, 2024c). Consistency for decreases in BWT associated with elevated exposure to PFOA and PFOS was supported by evidence from studies identified from the EPA's 2023 supplemental literature search. Specifically, for PFOA, seven studies identified from the 2023 literature search evaluated changes in BWT (i.e., BWT and BWT for sex and GA), and 4 out of 7 studies reported decreases with three of these studies reporting significant decreases (Section A.3 of USEPA, 2024a). Similarly, for PFOS, eight studies identified from the 2023 literature search evaluated changes in BWT (i.e., BWT and BWT for sex and GA), and four studies reported decreases, three of which were statistically significant (Section A.3 of USEPA, 2024b). These studies provided additional support for the critical effect of decreased BWT in multiple geographic locations (i.e., Denmark, the United States, and China).

Based on the results of the literature searches conducted through 2022, there was consistent evidence for decreased antibody response in children, particularly tetanus, diphtheria and rubella, associated with elevated exposure to PFOA and PFOS (see Sections 3.4.2 of USEPA, 2024d; USEPA, 2024c)). Studies from the Faroe Islands provided consistent evidence of associations between elevated exposure to PFOA and PFOS and decreases in antibody responses against tetanus and diphtheria in children at birth, 18 months, age 5 years (pre-and post-booster), and at age 7 years, with some associations being statistically significant (USEPA, 2024d; USEPA, 2024c, Sec. 3.4.2.1.2.1). Evidence from multiple Faroe Islands studies was supported by another study which reported an increased risk of being below the level of protection for diphtheria in participants from Greenland with elevated exposure to PFOA or PFOS (Timmerman et al., 2021). Additional support for immunosuppression was also reported in studies on decreased rubella in children. Specifically, for PFOA 2/2 studies measuring rubella antibodies in different populations demonstrated a significant decrease (see section 3.4.2.1.1 in USEPA, 2024a). For PFOS, 2/2 studies measuring rubella antibodies in different populations demonstrated a significant decrease (see section 3.4.2.1.1 in USEPA, 2024c). Consistency for decreased antibody responses in children associated with elevated exposure to PFOA and PFOS was further supported by evidence from an additional study identified in the EPA's 2023 supplemental literature search (see Section A.3 of USEPA, 2024a; USEPA, 2024b). One study examined elevated exposure to PFOA and PFOS and changes in antibody response in adolescents, and an effect was observed for both PFOA and PFOS (Zhang et al., 2023). A significant inverse association was observed for elevated exposure to PFOS and rubella antibody response in the overall study population, while a significant inverse association was observed for elevated exposure to PFOA and rubella antibody response for participants in the lower folate group. Zhang et al. (2023) provided additional evidence for decreased vaccine response in children to a pathogen besides those already identified (i.e., tetanus and diphtheria) and added to the existing evidence (i.e., Granum et al.,2013, Pilkerton et al., 2018 (for PFOA) and Stein et al., 2016).

Based on the results of the literature searches conducted through 2022, there was consistent evidence for increased ALT concentrations in adults associated with elevated exposure to PFOA and PFOS (see Sections 3.4.1 of USEPA, 2024d; USEPA, 2024c). Specifically, for PFOA, 9 out of 11 studies demonstrated statistically significant increases in ALT with elevated exposure to

PFOA was observed across studies. Similarly, for PFOS, 6 out of 9 studies demonstrated increased ALT concentrations in adults was associated with elevated exposure to PFOS and 5 of those studies were statistically significant increases. Consistency for increased ALT concentrations associated with elevated exposure to PFOA and PFOS was further supported by evidence from additional studies identified from the EPA's 2023 supplemental literature search. For PFOA, 3 out of 4 studies examining ALT reported increases in ALT and two of those studies were statistically significant increases (see Section A.3 of USEPA, 2024a). For PFOS, 3 out of 4 studies examining ALT reported increased ALT with one of these studies demonstrating a statistically significant increase (see Section A.3 of USEPA, 2024b). Together, these studies support the EPA's conclusion that the evidence indicates elevated exposures to PFOA or PFOS are associated with adverse hepatic effects, specifically increased liver enzymes, as well as EPA's selection of increased ALT in adults for dose-response modeling

4.2.1.1 General Comments

Harris County Attorney's Office (Doc. #1751, SBC-045261)

The proposed standards are needed to safeguard the health of our communities.

As EPA has noted, exposure to PFAS has been linked to many known health impacts. These negative impacts include issues with growth and development, hormone and lipid levels, the nervous system and the immune system, reproduction, the liver, and cancer. As such, HCA is in support of measures that can reduce PFAS's negative health impacts.

The volume of literature on these negative health effects is rapidly growing and continually points to the need to regulate these compounds. For example, a study published in April of this year concluded that elevated plasma concentration of certain PFAS is associated with increased weight gain and obesity. [FN1: Phillippe Grandjean et al., Weight loss relapse associated with exposure to perfluoroalkylate substances, Obesity, Spring 2023, at 1.] A study published in February suggested PFAS can disrupt certain biological processes in youth, which is connected to an increased risk of a very broad range of diseases, including developmental disorders, cardiovascular disease, metabolic disease, and many types of cancer. This study also notes that exposure to a mixture of PFAS, rather than a single chemical, drove the disruption of these biological processes. [FN2: See generally Jesse A. Goodrich et al., Metabolic Signatures of Youth Exposure to Mixtures of Per- and Polyfluoroalkyl Substances: A Multi-Cohort Study, 131(2) Feb. 2023, at 027005-1-14; Hope Hamashige, Keck School of Medicine study finds "forever chemicals" disrupt key biological processes, Keck Sch. Med. USC, (Feb. 21, 2/keck.usc.edu/keck-school-ofmedicine-study-finds-forever-chemicals-disrupt-key-biological-processes/.] Another study published in February of this year linked PFAS exposure to a decrease in female fertility. [FN3: Nathan J. Cohen, Exposure to perfluoroalkyl substances and women's fertility outcomes in a Singaporean population-based preconception cohort, 873 Sci. of the Total Env't, 162267 (2023) ("Higher PFAS exposures may be associated with decreased fertility in women")] The frequency in which a new negative health consequence is linked to PFAS signals the necessity of these regulations.

EPA Response: This commenter supports the conclusions of the EPA's toxicity assessments for PFOA and PFOS and has provided several citations to support this stance. Please see the EPA Response to 4.2.6 for information related to how the EPA considered references recommended during public comment. No further response needed.

Earthjustice et al. (Doc. #1808, SBC-046102)

EPA's proposed MCLGs are further supported by PFOA's and PFOS's severe noncancer effects, which occur at levels far below those that can be detected in drinking water. As recognized EPA's toxicity assessments for both PFOA and PFOS, those contaminants cause immune system harm (including reduced vaccine effectiveness in children), developmental toxicity, and heart and kidney damage at levels ranging as low as 3 ×10–8 mg/kg/day (PFOA) and 1 ×10–7 mg/kg/day (PFOS).63 Those levels equate to drinking water toxicity in the parts-perquadrillion range, well below the detection limit for either chemical.64 While cancer risks alone are sufficient to support the proposed zero ppt MCLGs for PFOA and PFOS, their serious noncancer risks reinforce the need for EPA to reduce exposure to both chemicals as much as feasible.

EPA Response: This commenter supports the conclusions of the EPA's proposed rule and toxicity assessments for PFOA and PFOS. No further response needed.

Midwest Environmental Advocates et al. (Doc. #1846, SBC-045823)

The six PFAS subject to this regulation may cause significant adverse impacts on human health.

The SDWA "was enacted to ensure that public water supply systems meet minimum national standards for the protection of public health." [FN4: Nat'l Wildlife Fed'n v. U.S. EPA, 980 F.2d 765, 768 (D.C. Cir. 1992).] The statute therefore requires EPA to base NPDWRs on a finding that a contaminant may have an adverse impact on human health. [FN5: 42 U.S.C. §§ 300g-1(a)(3), (b)(1)(A)(ii), (b)(1)(B)(ii)(II).] While our knowledge on the health effects of PFAS continues to grow, the best available scientific information supports the endangerment finding that each of the six PFAS contaminants at issue may cause adverse health effects.

EPA reviewed toxicity studies of oral exposure in animals and other reliable scientific data to reach the sound conclusion that each of these PFAS may cause adverse impacts to human health. [FN6: 88 Fed. Reg. 18638, 18645-47.] The word "may" in the endangerment criterion delineates the degree of certainty for EPA's finding, and it unambiguously requires merely a show of evidence indicating the "possibility or probability" [FN7: May, Merriam Webster Diction//www.merriam-webster.com/dictionary/may (last visited May 22, 2022); see also May, Cambridge Dictiononary.cambridge.org/us/dictionary/english/may (last visited May 23, 2022) (defining "may" as "used to express possibility"); see also Parker v. Scrap Metal Processors, Inc., 386 F.3d 993, 1015 (11th Cir. 2004) (noting that the word "may" in the endangerment finding of Section 107 of the Resource Conservation and Recovery Act clearly requires only a "potential" for harm or threat of harm).] of adverse human health effects. The notion that the endangerment criterion requires a quantifiable threshold of certainty regarding health impacts has been rejected.

[FN8: See Nat. Res. Def. Council, Inc. v. U.S. EPA, 824 F.2d 1211, 1217-18 (1987) (rejecting argument that SDWA requires a preponderance-of-the-evidence threshold test for regulating contaminants and emphasizing that "[b]y its terms, the statute grants discretion to the Administrator to determine whether there is sufficient evidence to justify establishing a recommended level for a particular compound.").]

The evidence relied upon by the agency to support its endangerment finding indicates a strong correlation between oral exposure to PFOS, PFOA, PFBS, PFHxS, PFNA, and GenX and certain adverse health effects, including cancers. Any claim that EPA lacks the required scientific data to proceed with this rulemaking therefore disregards not only the robust toxicological data on these PFAS, but also the plain meaning of the endangerment criterion, the health-protective design of SDWA, and the discretion conferred on the Agency to reach this determination.

Commenters support EPA's endangerment determination as a decision based on the "best available, peer-reviewed science and supporting studies" [FN9: 42 U.S.C. § 300g-1(b)(3)(A)(i).] and consistent with the protective statutory scheme of the SDWA.

EPA Response: This commenter supports the conclusions of the EPA's toxicity assessments for PFOA and PFOS and the preliminary regulatory determination presented in EPA's proposed rule (USEPA, 2023e). The EPA is issuing a final regulatory determination consistent with the comment (see section 3 of the EPA response in this *Response to Comments* document). The commenter appears to be using the term "endangerment finding" or "engagement criterion" or "endangerment determination" to refer to the regulatory criterion at section 1412(b)(1)(A)(ii). The EPA addresses its findings regarding that criterion in section III of tthis rulemaking preamble and section 3 of this *Response to Comments* document.

Silent Spring Institute (Doc. #1784, SBC-045799)

1. There is strong evidence of harm from low-dose exposures to PFOA and PFOS, including for sensitive subpopulations such as pregnant women, children, and nursing individuals.

EPA Response: This commenter supports the conclusions of the EPA's toxicity assessments for PFOA and PFOS, specifically that sensitive populations may be at risk of adverse health effects. No further response needed.

Silent Spring Institute (Doc. #1784, SBC-053335)

Regardless of these omissions, EPA's conclusion of low-dose toxicity of PFOA and PFOS is consistent with the conclusion of the European Food Safety Authority in its 2020 assessment of four PFAS. In the revised opinion on joint exposures to PFOA, PFNA, PFHxS and PFOS, EFSA considered immunotoxicity as the critical effect and calculated a tolerable daily intake limit of 0.63 ng/kg-day.21 Using Lifetime Health Advisory formula from EPA, this intake limit corresponds to a health-based drinking water concentration limit of 2 ng/L for the sum of PFOA,

PFNA, PFHxS and PFOS. These data highlight the need to set the MCLs for PFOA and PFOS to levels as low as feasible to be protective of the most sensitive health effects.

EPA Response: This commenter supports the conclusions of the EPA's toxicity assessments for PFOA and PFOS and has cited conclusions by the EFSA (EFSA, 2020) to support their rationale. Please see the EPA Response to 4.2.6 below for information related to how the EPA considered conclusions from other health agencies when finalizing the toxicity assessments. No further response needed.

New Jersey Department of Environmental Protection (NJDEP) (Doc. #1699, SBC-045013 & SBC-045014)

Derivation of Maximum Contaminant Levels and Hazard Index

MCLGs for PFOA & PFOS

EPA requested comment on the derivation of the proposed Maximum Contaminant Level Goals (MCLGs) for PFOA and PFOS. The proposed rule (88 Fed. Reg. 18652) states that, based on recommendations from the EPA Science Advisory Board (SAB), EPA's quantitative analysis for PFOA and PFOS focused on the five health outcomes with the strongest weight of evidence—liver, immune, cardiovascular, developmental, and cancer. The DWQI (2022) also concluded that these are the five health outcomes with the strongest evidence for PFOA and PFOS, and NJDEP concurs with this conclusion.

Use of human data as the basis for PFOA and PFOS toxicity factors:

The proposed rule (88 Fed. Reg. 18657) states: "…when both laboratory animal data and human data with sufficient information to perform exposure-response modeling are available, human data are generally preferred for the derivation of toxicity values." Regarding this point, the DWQI (2022) evaluated relevant information and agreed with EPA's conclusion that human data are an appropriate basis for the derivation of Reference Doses for non-carcinogenic effects of PFOA and PFOS and the cancer slope factor for carcinogenic effects of PFOA, and NJDEP concurs with the DWQI (2022) conclusion.

EPA Response: This commenter supports the conclusions of the EPA's toxicity assessments for PFOA and PFOS, specifically that the hepatic, developmental, immune, cardiovascular, and cancer health outcomes are those with the strongest supporting evidence and that human data are an appropriate basis for toxicity value derivation. No further response needed.

Steven Alt (Doc. #1724, SBC-044472)

The following represent my opinions and beliefs:

I support the EPA proposal to establish standards for PFAS in public drinking water supplies. I am a private citizen who believes strongly in learning from history. I read PFAS are endocrine

disruptors and the CDC stated “Endocrine disruptors are a particularly relevant environmental exposure, as exposure results in a decrease in testosterone and fewer males are conceived as a result.” [FN1: ,Hartnett KP, Marcus M. Can environmental or occupational hazards alter the sex ratio at birth? A systematic review. Emerg Health Threats J. 2011;4:7109.] A quick check of the Ccking.cdc.gov/DataExplorer on sex ratio led me to believe sex ratio skewing of humans has been occurring in WI counties deriving their drinking water supply from Lake Michigan which also supports my personal observation of more females seemingly being born than males in areas drawing drinking water from Lake Michigan.

I am disappointed in what I believe was the delay in the heeding of the possible warning signs, the first nearly 40 years ago and a second ~25 years ago. I do not know the level of communication between the EPA and State agencies such as Department of Natural Resources (DNR), but I believe strong warning signs of a new harmful pollutant (PFAS) in Lake Michigan might have been ignored in the past. I felt and still feel Great Lakes native aquatic species act much like the ‘canary in the coal mine’, a sentinel species, warning of possible environmental danger. The first warning, the Wisconsin Department of Natural Resources (WDNR) referenced in 1999 [FN2: The Great Lakes Fishery Commission; Lake Michigan Committee; Lake Michigan Management Reports, Lake Michigan Fisheries Team 1999. See Attachment2_WDNR_Manag_Rpt_1999], a document concerning Lake Michigan, page 12 “The substantial shift in sex ratios that has occurred since 1980 continued in the chub population sampled during 1998 from GMGN. In the early 80’s when younger fish (ages 2-5) dominated the chub population, the sex ratio was about 50:50. Now, with a greater range of year classes in the population, which older fish dominate, females predominate. The one advantage of the female dominated sex ratio to the industry is that commercial fishers have profited through the sale of eggs to the caviar market during the late fall and winter months”. I could not find any natural process which could explain this, nor could I find sex ratio skewing reported in Lake Michigan fisheries previously. I felt a chemical pollutant best explained this, but the list of past chemical contaminates such at DDT, Dioxin, mercury, etc. already being present for decades didn’t seem to result in fish skewing female so greatly and quickly, as chubs did in ‘the early 80’s’, while I believed PFAS could.

The second warning around the same time; in 1996 WI temporarily banned the netting of yellow perch in Lake Michigan [FN3: Excluding Green Bay (GB)] . Per perch surveys [FN4: Winter Graded-Mesh Assessments and or Statistical Catch At Age SCAA starting in 1986 for Lake Michigan (ex. GB)] , up until 1996 the yellow perch were skewing male most likely due to netting, as later supported by Lauer [brary.wiley.com/doi/abs/10.1111/j.1365-2400.2007.00567.x Changes in yellow perch length frequencies and sex ratios following closure of the commercial fishery and reduction in sport bag limits in southern Lake Michigan] . My fears of a chemical pollutant were further reinforced as can be seen from the Lake Michigan Yellow Perch Task Group 2021 report [mprey.org/pubs/lake_committees/michigan/yellow_perch/Status%20of%20YEP%20in%20LM%202019-2020%20(2021).pdf page 8 figure 2] , starting in 1997 the perch sex ratio immediately skewed female, a condition no longer hidden by the netting of female perch. Just as done

previously with chubs, the WDNR tried to spin this worrisome fact by stating “Since 2000 the sex ratio of the yellow perch population was shifted toward predominantly female and lasted until 2002. This trend was reversed again since 2003 with greater number of males, except for 2007. But recently the female proportion has increased markedly with 71% in 2010, 76% in 2011, 77% in 2012, and 76% in 2013. The data from 2008-2012 spawning assessment also indicated a decreased number male perch in the population. An absence of commercial harvest in Lake Michigan certainly has helped decrease the impact on fast growing larger female perch in the fishery, allowing them to spawn multiple years.” [FN7: Lake Michigan Management Reports – 2013 WdNR. Page 18. See Attachment3_WDNR_Manag_Rpt_2013.pdf] Spawning multiple years was never previously mentioned by the WDNR as being of concern. Also of possible interest to researchers, the stated 2003 ‘reversed trend’ coincided with the perch raised allegedly for a WDNR/UW Water Institute Yellow perch Broodstock program [FN8: See attachment5_Yellowperch1997broodstock.pdf] started in 1997 using yellow perch eggs removed from the Milwaukee reef. While the WDNR admits to UW Water Inst. Producing 195 liters (~16 million) Lake Michigan strain yellow perch eggs, the final disposition of those eggs and/or resulting fry [//dnr.wisconsin.gov/sites/default/files/topic/Fishing/LM_LakeMichiganYellowPerchSummitReport.pdf bottom page 21.] was withheld. This temporary pause of WI perch skewing female I believe was due to the unreported stocking of above perch in Lake Michigan (reported stockings [F//dnr.wi.gov/fisheriesmanagement/Public/Summary/Index In 1978 - 178,740 (inland strain) and 1981 - 200,000 (Green Bay strain) perch were stocked in Lake Michigan off Milwaukee Co.] led to the pervious perch recovery by 1986) and so offers a vein of investigation comparing the sex ratio of fish which spawn in Lake Michigan vs those which move up its tributaries to spawn.

I found the WDNR’s concern for the profits of apparent illegally subsidized commercial fishing [Fs://p.widencdn.net/2gge3j/Admin_FH039 Administrative Report No. 39 Lake Michigan Integrated Fisheries Management Plan 1995 – 2001 Feb 1995, page 38, ‘may not be appropriate’, i.e. illegal as it apparently violates WI Law of 1977 Act 418 (37) (d) 3 which requires ‘…an economically viable and stable commercial fishe/docs.legis.wisconsin.gov/1977/related/acts/418.pdf page 1799.] over the ecology of the lake, the health of a major fish species, such as chubs and perch, and possible danger to humans, worrisome, since a totally female population also leads to extinction.

One problem experienced in my private research into Lake Michigan’s fish skewing by sex ratio is and has been Wisconsin’s apparent lack of concern of laws [FN12: Law of 1977 Act 418 (37) (d) 3; reported again l//www.jsonline.com/story/sports/outdoors/2017/02/04/conservation-groups-urge-increases-licensefees/97360920/ paragraph 3, “The funding now comes from sportsmens' dollars”.] /statute [FN13: Sections 29.014(1), 29.041, and or 29.519 (1m) (b), Wis. Stats: commercial limits in excess of harvestabil/docs.legis.wisconsin.gov/code/register/2015/714B/register/rule_notices/cr_15_050_hearing_information/cr_15_050_rule_text - “... making the current Wisconsin harvest limit outdated and unsustainable”. Note: requested change was rejected, so limit is still outdated, unsustainable and/or in violation of law.]

/rules/agreement(s)s://docs.legis.wisconsin.gov/code/misc/chr/lrb_scanned/cr_96_098_final_rule_filed_with_lrb.pdf required a commercial limit of 7,140 in the future; money was paid but limit was raised starting in 2002, currently is 10,300.] concerning WI commercial fishing laws being violated, sciencettps://p.widencdn.net/cejkm3/03-01-NRB-minutes NRB meeting page 22-24. WDNR states a GB perch population of less than ~1.9 million requires a commercial limit of 20,000/yr. ,yet since 2008 with the population at less than 1.9 million the GB perch limit is at 100,000 lbs./yr. per WDNR GB perch SCAA dated 2022.] and/or data being ignored and/or purposely changed [FN16: 6 Attachment6_WDNR_GB_Population_estimates_from_SCAA_including_yearlings_1978-2013. WDNR SCAA's 2008-2013 Green Bay stated age-1 perch numbered 149,232,000 perch with a biomass of 12,004,700 lbs., making the 2008 age1 perch the largest in history of the SCAA. In 2016 the number was changed to just 860,410 age-1 perch reported and in 2022 reported 1,46,270 age-1 perch reported present instead.]. The WDNR downplays by 10 fold the past damage to the perch fisherylberglab.cbl.umces.edu/pubs/wilberg%20et%20al%20yellow%20perch%20dynamics%20NAJFM%202005.pdf by Wilberg 2tp://www.great-lakes.org/can_am.html], to the public, via a newspaper article [FN18: tps://www.jsonline.com/story/sports/columnists/paul-smith/2018/07/27/paul-smith-lake-michigan-yellow-perchdire-straights/834668002/ see graph labeled 'CPE of yellow perch – WI (GMA)', Note Y-Axis 'CPE per 1000 ft. of gillnet' is in units of 100 not the historically recorded 1,000] and/or their current management reportsps://dnr.wisconsin.gov/sites/default/files/topic/Fishing/LM_GLFCReport2022.pdf Figure 6 page 105.] both of which have a Y-Axis 'CPE per 1000 ft. of gillnet' in units of 100. Whereas the numbers on their websiteps://dnr.wisconsin.gov/topic/Fishing/lakemichigan/Yellowperch.html], past reports [FN21: One example: Attachment2_WDNR_Manag_Rpt_1999 page 29.] and shared with the Lake Michigan Yellow Perch Task Groualamprey.org/pubs/lake_committees/michigan/yellow_perch/Status%20of%20YEP%20in%20LM%202019-2020%20(2021).pdf] has CPE reported correctly, in 1,000's. The WDNR also underreported the WI commercial perch harvest for 2012 [FN22: See Attachment3_WDNR_Manag_Rpt_2013 page 15- 'In 2012, commercial fishers harvested a total of 57,845 pounds...']& 2013 [FN23: Attachment4_WDNR_Manag_Rpt_2014 page 5 of 49- "In 2013, commercial fishers harvested a total of 73,452 pounds (223,528 fish) of yellow perch using gill nets and drop nets, compared to 57,845 pounds in 2012 (Figure 4)".] to the public, but correct numbers to N.sciencebase.gov/catalog/item/5b99907ce4b0d966b4842829 Per noaa12.txt Lake Michigan perch harvest was 64,503 lbs. in 2012 and per noaa13.txt was 80,807 lbs. in 2013.]. Based on history I worry as to the accuracy and thereby the usefulness of any WDNR scientific findings in relation to any research involved with any federal agency, EPA, USFWS, etc. Due to the timing I also believe the Lake Michigan diporeia decline may also be due to sex ratio skewing.

I believe Great Lakes aquatics are sentinel species, and I fear their depletion since Lake Michigan fisheries numbers have declined up to 9

.glfc.org/pubs/lake_committees/common_docs/LM_Forage_Report_2021_For_Dissemination.pdf] since WI went to a commercial fishing quota system in 1989. There are basically no chubs, perch and smelt left in the lake to be used for surveys and science. I fear our denial of fish sentinels due to WI politics, such as 2011 ABttps://docs.legis.wisconsin.gov/2011/related/public_hearing_records/ac_natural_resources/bills_resolutions/11hr_ac_nr_ab0176_pt01.pdf AB176 repealed the minimum harvest requirement for WI commercial fishermen; AB176 did not make WI commercial fishing compliant with WI Law of 1977 Act 418 (37) (d) 3 though it was referenced, as was its being ignored (page 11)], which sought to protect too many WI commercial fishers from too few fish, instead of protecting the few fish left by upholding all WI laws. I don't know the scientific exchange between WI and EPA, if any, but I have a real fear that by ignoring laws and science WI might have contributed to the delay/accuracy of any investigation into the possibility of PFAS skewing fisheries, and humans, to female.

While I cannot find any research pointing to PFAS contributing or being responsible for some Lake Michigan fisheries skewing female, I believe removing PFAS from drinking water will be of help to future researchers by monitoring any changes in the sex ratios of fish, (and humans), such as perch using reefs near large metropolitan cities, like Milwaukee, where drinking water with lower levels of PFAS would be returned via city waste water, offering a comparison of pre vs post PFAS regulation of drinking water.

EPA Response: This commenter supports the conclusions of the EPA's toxicity assessments for PFOA and PFOS and has provided several citations to support this stance. Please see the EPA Response to 4.2.6 below for information related to how the EPA considered references recommended during public comment. Commercial fishing and/or fishery contamination by PFAS or other endocrine disruptors are beyond the scope of this drinking water regulatory action, as are Wisconsin's regulation of fisheries or their efforts to conduct biological surveys of fisheries. Additionally, historical contamination of Lake Michigan by potential endocrine disrupting chemicals is also beyond the scope of this drinking water regulatory action.

3M Company (Doc. #1774, SBC-045685)

d. EPA's Approach to Assessing the Overall Weight of Evidence for Non-Cancer Health Effects of PFOA and PFOS is Not Consistent with Guidance and Methods are Neither Transparent nor Reproducible

EPA likewise did not follow its own guidance in determining that PFOA and PFOS exposure is associated with numerous noncancer health effects including, but not limited to: "effects on the liver (e.g., liver cell death), growth and development (e.g., low birth weight), hormone levels, kidney, immune system, lipid levels (e.g., high cholesterol), the nervous system, and reproduction." For each type of health effect listed, EPA has not followed its own guidance (i.e., the IRIS Handbook) in evaluating the weight of evidence of the science, which shows, at most, inconsistent associations of the effects with PFOS and PFOA exposures. For several endpoints,

EPA improperly conflates changes in biomarkers (e.g., antibody response, cholesterol, liver enzymes) with increased risk of adverse disease outcomes in humans.

Agencies cannot disregard available scientific evidence that is better than the evidence on which it relies. [FN69: Kern County Farm Bureau v. Allen, 450 F.3d 1072, 1080 (9th Cir.2006).] However, this is exactly what EPA did in this Proposed Rule. As summarized below, EPA disregarded legitimate studies for reasons that are unclear or not justified in its Proposed Rule. [FN70: Ultimately, "[t]he presumption of agency expertise may be rebutted if the agency's decisions, although based on scientific experience, are not reasoned." Greenpeace v. NMFS, 80 F.Supp.2d 1137, 1147 (W.D. Wash. 2000).] Key scientific evidence and uncertainties for each health endpoint as well as EPA's failure to properly review and evaluate the evidence are summarized below, using immune system effects as an example.

In EPA's draft toxicity assessments for PFOA and PFOS (USEPA 2023a,b), EPA derived multiple candidate RfDs across four non-cancer health outcomes comprising four endpoints (i.e., decreased antibody response, low birth weight, increased total cholesterol, and elevated alanine transaminase (ALT) 71) from both epidemiological and animal toxicological studies that EPA deemed to have the "strongest weight of evidence" (USEPA 2023a,b). However, as described in Sections V.d – V.f above, EPA's process failures mean that none of these endpoints are, in fact, supported by the weight of evidence. Nonetheless, EPA determined that "candidate RfDs derived from epidemiological studies were all within 1 order of magnitude of each other (10-7 to 10-8 mg/kg/day), regardless of endpoint, health outcome, or study population . . . In fact, [for PFOA] candidate RfDs within the immune, developmental, and cardiovascular outcomes are the same value" (USEPA 2023a). EPA made similar conclusions for PFOS, as the candidate RfDs based on epidemiological studies "within the developmental and cardiovascular outcomes are the same value" (USEPA 2023b). As a result, EPA selected an overall RfD of 3 x 10-8 mg/kg/day for PFOA and 1 x 10-7 for PFOS.

As described in the following discussion, the range of estimated RfD values for PFOA that account for uncertainty is quite large. If uncertainties in each step of RfD derivation were estimated for each of the "co-critical endpoints" identified by EPA, it is unlikely that the resulting range of RfD values for each co-critical endpoint would be the same. To further increase confidence in the overall RfD, best practice would be to calculate ranges of RfD values that account for uncertainties within each of the endpoints identified as co-critical.

EPA Response: The EPA disagrees with the claims that the PFOA and PFOS toxicity assessment methods were inconsistent with EPA guidance and practice. Regarding the EPA's approach and methods used to conduct these assessments and how the EPA was consistent with agency guidance, see the EPA Response to 4.1.1 and 4.2.2. as well as the individual EPA responses to comment Doc. #1774, SBC-053146SBC-045649 & SBC-045650; Doc. #1774, SBC -045660; Doc. #1774, SBC-053425; Doc. #1774, SBC-045661; Doc. #1774, SBC-053426; Doc. #1542, SBC-043344, Doc. #1542, SBC-043350, Doc. #1774, SBC-045649, Doc. #1774, SBC-053417, Doc. #1774, SBC-045680, Doc. #1774, SBC-053418 & SBC-045681, Doc. #1774, SBC-045701, and Doc. #1774, SBC-045702. The EPA addresses concerns regarding the

consistency of the database and how the EPA evaluated individual studies in the EPA Response to 4.2.1.1 above and the EPA responses to specific endpoints below (see all of the EPA response in the following subheadings on low birth weight (LBW) (4.2.1.2), total cholesterol (4.2.1.3), antibody response (4.2.1.4), and ALT (4.2.1.5))), as well as the EPA response to the adversity of the selected critical effects in section 4.2.2.2.2.

The commenter incorrectly stated that the EPA derived candidate RfDs for only four endpoints from epidemiological and animal toxicological studies in the PFOA and PFOS public comment draft toxicity assessments (USEPA, 2023f; USEPA, 2023a). In fact, the EPA considered 9 different outcomes based on 26 different endpoints and studies (see Table 4-8 in USEPA, 2023f) in the derivation of PODs resulting in 15 candidate RfDs for PFOA (see Table 4-11 in USEPA, 2023f) and 10 different outcomes based on 24 different endpoints and studies (see Table 4-8 in USEPA, 2023a) in the derivation of PODs resulting in 14 candidate RfDs for PFOS (see Table 4-11 in USEPA, 2023f). These were clearly described in Section 4 of the PFOA and PFOS toxicity assessments (USEPA, 2023f; USEPA, 2023a). Based on an updated literature search and feedback from public comment, the EPA expanded the number of endpoints and studies considered for POD derivation to 30for PFOA (see Table 4-8 in USEPA, 2024d) and 29for PFOS (see Table 4-8 in USEPA, 2024c) resulting in 15 candidate RfDs for PFOA and 16 candidate RfDs for PFOS in the final toxicity assessments (USEPA, 2024d; USEPA, 2024b).

The commenter also recommended that the EPA calculate "ranges of RfD values that account for uncertainties within each of the endpoints identified as co-critical," claiming that this would be best practice. The EPA disagrees that the approach recommended by the commenter is standard or best practice for the agency and the commenter does not provide a citation verifying this claim. To derive the RfDs for PFOA and PFOS, the EPA followed established Agency methods and guidance, none of which describe a range of RfDs as "best practice" (USEPA, 2022a; USEPA, 2002a; USEPA, 2014a). The EPA accounted for uncertainties in the co-critical endpoints by deriving multiple PODs from multiple studies in varied populations, conducting sensitivity analyses, and deriving multiple candidate RfDs for each epidemiological endpoint and health outcome (see Appendix E and Section 4 of USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). As described in Section 4.1.6 of the PFOA and PFOS toxicity assessments, "the candidate RfDs derived from epidemiological studies were all within 1 order of magnitude of each other, regardless of endpoint, health outcome, or study population," thus increasing the EPA's confidence in and decreasing uncertainty of these values and limiting how informative a "range" of RfDs would be (USEPA, 2024d; USEPA, 2024c). Responses to the commenter's suggestions of uncertainties for specific health outcomes are outlined in 4.2.1.2 Consideration of Decreased Birthweight as a Critical Effect, 4.2.1.3 Consideration of Serum Lipids as a Critical Effect, 4.2.1.4 Consideration of Decreased Antibody Response as a Critical Effect, and 4.2.1.5 Consideration of Increased ALT as a Critical Effect).

American Chemistry Council (ACC) (Doc. #1711, SBC-044459)

[The Agency's proposal suffers from the following significant shortcomings –]

The Agency's assessment of the non-cancer health effects of PFOA and PFOS inappropriately and selectively relies on data from a limited number of epidemiology studies, all of which provide limited support for a causal relationship between exposure and an adverse health impact

EPA Response: The commenter incorrectly stated that the EPA's assessment relied on "data from a limited number of epidemiological studies." As described in Sections 2, 3, and 4 of the PFOA and PFOS toxicity assessments (USEPA, 2023f; USEPA, 2023a), the EPA relied on three evidence streams to conduct hazard identification (i.e., epidemiological, animal toxicological, and mechanistic studies) and relied on both epidemiological and animal toxicological data, combined totaling hundreds of studies, to serve as the basis of the hazard conclusions. Through this approach, the EPA determined that the evidence indicates that PFOA and PFOS **likely causes** immune, developmental, hepatic and cardiovascular effects in humans consistent with the ORD IRIS Handbook (USEPA, 2022a). See section 4.2.1 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1738, SBC-047706 in section 13.4 of this *Response to Comments* document.

American Chemistry Council (Doc. #1841, SBC-044832)

EPA Overstates the Non-Cancer Risks Associated with PFOA and PFOS Exposure

EPA's assessment of non-cancer health effects for both PFOA and PFOS relies on the same set of eight epidemiology studies that have reported immune, developmental, cardiovascular, and hepatic effects. The analysis for immune effects focuses on reports of decreased antibody levels among children in genetically isolated populations that have not been associated with an increase in infection. Similarly, the reports of cardiovascular effects stem from reports of increased cholesterol levels in the absence of an association with heart disease and the reports of hepatic effects are based on changes in liver enzymes but not an increase in liver disease. Correlation to liver effects observed in animal studies is complicated by the likely contribution of a rodent-specific response that may not be relevant to human risk assessment. The results from studies of developmental effects are mixed, with the majority of studies reporting no association with the endpoint modeled by EPA. These types of endpoints – changes that may be reversible, potentially not adverse to humans, and that do not result in disease – are not suitable for drinking water MCL development, based on existing EPA health risk assessment guidance.

EPA Response: The commenter incorrectly claims that the EPA "relies on the same set of eight" epidemiologic studies in the assessment of non-cancer health effects hazards. This is incorrect because the EPA qualitatively relied on hundreds of studies to support the noncancer health conclusions of the PFOA and PFOS toxicity assessments as described in section 3 of the toxicity assessments (USEPA, 2023f; USEPA, 2023a). The EPA quantitatively considered nine epidemiological studies for candidate RfD derivation for PFOA, as illustrated in Figure 4-4 (USEPA, 2023f). The EPA additionally considered four different animal toxicological studies for candidate RfD derivation for both PFOA and PFOS (USEPA, 2023f; USEPA, 2023a).

Regarding "genetically isolated populations," the commenter does not provide any support as to how the population of the Faroe Islands would respond to PFOA or PFOS exposure differently than any other population. Please also see the EPA response to 4.2.2.1 1 Derivation of the Noncancer Reference Doses (RfDs) and EPA Responses to section 4.2.2.2.3. Regarding EPA's selection of critical effects, and particularly, the selection of biomarkers or precursor effects, please see Section 4.2.2.1 of the EPA response in this *Response to Comments* document and section 4.2.2.2.2 of the EPA response in this *Response to Comments* document. Responses to health outcome-specific comments, such as the human relevance of liver effects observed in animals (see section 4.2.1.5 of the EPA response in this *Response to Comments* document) and the evidence base for developmental effects (see section 4.2.1.2 of the EPA response in this *Response to Comments* document), are provided in the subsections below.

In contrast to the commenter's claims, the EPA followed established human health risk assessment methods (e.g., USEPA, 2022a) to review the available evidence for each health outcome, select critical effects and studies, and make conclusions regarding the potential adversity of effects (see EPA responses to 4.1.2 The EPA's Use of the Best Available Science, EPA Guidance, and Data Quality Control Practices). Regarding "rodent-specific response[s]," please see the EPA response to comment Doc. #1774, SBC-045682, Doc. #1774, SBC-045683, and Doc. #1774, SBC-053196.

American Farm Bureau Federation et al. (Doc. #1642, SBC-043502) (repeated by Illinois Farm Bureau (Doc. #1630, SBC-043143))

The Research on PFAS Is Still Ongoing

As we previously stated, our society cannot dismiss the health concerns related to PFAS exposure and the research in this space must continue. However, even EPA cannot definitively assert that PFAS exposure is leading to these adverse health outcomes. According to EPA's website: "Current scientific research suggests that exposure to high levels of certain PFAS may lead to adverse health outcomes. However, research is still ongoing to determine how different levels of exposure to different PFAS can lead to a variety of health effects. Research is also underway to better understand the health effects associated with low levels of exposure to PFAS over long periods of time, especially in children."

Additionally, the EPA states that the "health effects are difficult to determine." Given the costs that drinking water utilities must expend, which will ultimately land on the backs of American families, we believe EPA needs to improve the transparency of their review of studies and update their assessments based on availability of human studies to ensure the limit they regulate is both in line with the best science on health impacts but also takes into consideration the feasibility of implementation.

EPA Response: Please see the EPA Response to 4.2.1. Additionally, the commenter misleadingly quotes the EPA's website and statement on PFAS (https://www.epa.gov/pfas/our-current-understanding-human-health-and-environmental-risks-pfas) out of context. The full

quote states (emphasis added to text commenter omitted):
"Current scientific research suggests that exposure to certain PFAS may lead to adverse health outcomes. However, research is still ongoing to determine how different levels of exposure to different PFAS can lead to a variety of health effects. Research is also underway to better understand the health effects associated with low levels of exposure to PFAS over long periods of time, especially in children.

What We Know about Health Effects

Reproductive effects such as decreased fertility or increased high blood pressure in pregnant women.

Developmental effects or delays in children, including LBW, accelerated puberty, bone variations, or behavioral changes.

Increased risk of some cancers, including prostate, kidney, and testicular cancers.

Reduced ability of the body's immune system to fight infections, including reduced vaccine response.

Interference with the body's natural hormones.

Increased cholesterol levels and/or risk of obesity.

***Additional* Health Effects are Difficult to Determine**

Scientists at the EPA, in other federal agencies, and in academia and industry are continuing to conduct and review the growing body of research about PFAS. However, health effects associated with exposure to PFAS are difficult to specify for many reasons, such as:

There are thousands of PFAS with potentially varying effects and toxicity levels, yet most studies focus on a limited number of better known PFAS compounds.

People can be exposed to PFAS in different ways and at different stages of their life.

The types and uses of PFAS change over time, which makes it challenging to track and assess how exposure to these chemicals occurs and how they will affect human health."

The portion quoted by the commenter that implies all health effects are difficult to determine, is in fact an excerpt from a header that starts with the word "additional," after having listing numerous health effects associated with PFAS. The EPA also notes that PFOA and PFOS are two of the "limited number of better known PFAS compounds." Despite the commenter's misrepresentative claims otherwise, the EPA has determined that there are data available to make qualitative and quantitative conclusions about numerous adverse health effects associated with PFOA and PFOS exposure. PFHxS, PFNA, HFPO-DA, and PFBS also have been associated with numerous adverse health effects, as highlighted in USEPA, 2021d; USEPA, 2021e; ATSDR, 2021, and further discussed in section IV of the preamble of the PFAS drinking water regulation and section 4.3 of the EPA response in this *Response to Comments* document.

4.2.1.2 Consideration of Decreased Birthweight as a Critical Effect

3M Company (Doc. #1774, SBC-053211)

ii. EPA's assessment of developmental effects is flawed

In evaluating the impacts of PFOA/PFOS on development effects (namely, low birth weight), EPA did not appropriately employ methods described in the IRIS Guidance for evaluation of study quality and risk of bias.

EPA (USEPA 2023a,b) considered associations between PFOA and PFOS exposures and multiple developmental outcomes, including birth weight, birth length, head circumference, diagnosed condition of low birth weight,74 or small for gestational age, 75 gestational duration, or diagnosed conditions such as preterm birth. 76 EPA determined that there was moderate evidence of an association between PFOA or PFOS and developmental effects based on epidemiologic literature. As discussed below, this determination was not supported by the underlying evidence and appears to be based primarily on inconsistently observed decreases in birth weight.

EPA also did not appropriately consider uncertainties – most of which directly implicate bias in studies' results. These uncertainties include:

· Potential bias due to pregnancy hemodynamics and sample timing

· Mixed evidence for gestational duration, measured as gestational age or preterm birth

· Inconsistent evidence with rapid growth measures, including postnatal height and adiposity up to age 2

· Little evidence for increased fetal loss

· No evidence for increased birth defects

· Limited dose-response evidence in birth weight deficit studies

Additional details regarding the strength of evidence related to developmental outcomes are described in the EPA Evidence Stream and Summary Judgments (USEPA 2023a Table 3-10; USEPA 2023b, Table 3-12). EPA's determination of a "moderate" level of evidence is not supported by the findings presented. Decreases in birth weight have not been shown to represent adverse effects or other clinically meaningful health effects. In the appraisal of study quality and risk of bias, EPA did not evaluate studies consistently, which led to the selection of candidate studies for POD development with critical limitations. PODs are estimates of the dose levels at which an adverse response is not expected; they are typically derived near the low end of the observable range of data by using dose-response analyses within the selected studies. The PODs are then used as the basis for toxicity value calculations. Selection of reliable studies with limited bias is critically important for limiting the uncertainty in the derived POD and subsequent toxicity values.

1. Evidence integration of developmental outcomes demonstrated inconsistent evidence for an effect from PFOA/PFOS exposure.

EPA's categorization of the evidence regarding developmental outcomes is inconsistent with EPA's own criteria for an evidence synthesis judgement of "moderate" evidence in human studies. In order for evidence to be characterized as "moderate," the IRIS Handbook states that the evidence "includes at least one high or medium confidence study reporting an association and additional information increasing certainty in the evidence. For multiple studies, there is primarily consistent evidence of an association with reasonable support for adversity, but there might be some uncertainty due to potential chance, bias, or confounding or because of the indirectness of some measures" (USEPA ORD 2022, Table 6-4). IRIS guidance also states that supplementary evidence may address some of the uncertainty factors and raise a set of studies from "slight" to "moderate" evidence rating. Given the lack of consistency in the scientific literature, it is unclear how EPA concluded that there is "moderate" evidence that PFOA/PFOS affect developmental outcomes.

Moreover, EPA's determination of "moderate" evidence for developmental outcomes is a broad judgement that obscures the fact that such a designation is not consistent with EPA guidance for specific categories such as birth weight, birth length, head circumference, LBW, SGA, gestational duration, fetal loss, post-natal growth, and birth defects (USEPA 2023a Table 3-10; USEPA 2023a Table 3-12). EPA presented inconsistent or limited evidence of associations between PFOA/PFOS and each of the specific developmental outcomes, and did not provide judgements for any one of the specific developmental outcomes separately. Therefore, the strength of each evidence base is unclear.

In reviewing EPA's draft documents, the SAB stated that it was "not aware of evidence for associations of PFOA and PFOS with adverse consequences such as developmental delays in low birth weight/small for gestational age infants." (USEPA SAB 2023, p. 21). In short, EPA did not show consistent evidence that met the criteria for "moderate" evidence of an association between PFOA or PFOS exposure and developmental outcomes. Yet despite the uncertainties in the evidence of a relationship between PFOA or PFOS exposure and developmental outcomes, as acknowledged by EPA's own SAB, EPA selected decreases in birth weight as a critical endpoint and used it in POD derivation. Best practice is for EPA to follow its own guidance and determine evidence judgements for specific outcomes to select appropriate critical endpoints.

2. EPA did not appropriately consider the lack of consistency or plausibility demonstrated within the evidence base for decreased birth weight and incidence of adverse effects such as small for gestational age or low birth weight.

In reviewing EPA's draft documents, SAB recommended that EPA "clearly demonstrate that the endpoints selected for POD development are well established, sensitive, adverse or precursor to adverse"" (USEPA 2023c, p. 20). Due to the lack of evidence for associations between PFOA and PFOS exposure and developmental outcomes (e.g., fetal loss or birth defects), lack of consistency in evidence for outcomes of LBW or SGA, and lack of evidence that measured

decreases in birth weight are clinically relevant developmental outcomes, EPA has failed to meet the standard SAB deemed appropriate.

Two thirds of the studies (6 of 9) for PFOA showed some increased risk of either SGA or LBW, but did not have statistically significant results, meaning those studies are not reliable predictors of developmental effects. Critically, only 5 of the 11 examined PFOA in early pregnancy, which is the only period of exposure timing that is considered a lower risk of bias due to changes in pregnancy hemodynamics (Meng et al. 2018; Hjermitslev et al. 2020; ManzanoSalgado et al. 2017; Wikstrom et al. 2020; Chang et al. 2022). Of these 5 studies, only 2 identified statistically significant associations (Wikstrom et al. 2020; Chang et al. 2022). Of those, EPA selected one as a candidate study (Wikstrom et al. 2020). However, serum volume increases by about 50% during pregnancy, peaking at 30-35 weeks gestation (Salas et al. 2006), and glomerular filtration rate (GFR) increases similarly (40-50%) (Cheung and Lafayette 2013). These increases lead to a decrease in maternal serum PFAS concentration during pregnancy (Monroy et al. 2008; Steenland et al. 2018; Kato et al. 2014) and the magnitude of increases can be inversely correlated with birth weight. First trimester serum PFAS measures have less chance for bias from sample timing (USEPA 2023a, p. 3-212). Additionally, two meta-analyses by Dzierlenga et al. (2020) and Steenland et al. (2018) found that when PFOA was measured in early pregnancy, there was little to no association with LBW, suggesting that the timing of serum measurement is critical for accurate interpretation of study results.

While EPA described the collective evidence as "supportive" of an increased risk of LBW or SGA with PFOA/PFOS exposure, this is inconsistent with the fact that less than half of the studies reported statistically significant results, demonstrating that there was not consistent evidence of an association between PFOA/PFOS and these outcomes. Among the studies for PFOS, 5 of 10 studies examined PFAS measured in early pregnancy (Meng et al. 2018; Hjermitslev et al. 2019; Manzano-Salgado et al. 2017; Wikstrom et al. 2020; Chang et al. 2022), one of which was selected as a candidate study. Of the 5 studies, 2 reported statistically significant associations. Of the 7 high- or medium confidence studies, 2 reported statistically significant increased risks of SGA and only 2 of the 4 high- or medium-confidence studies reported increased risks of LBW (USEPA 2023b, p. 3-206-210).

EPA considered 6 high confidence studies of PFOA for POD development (Chu et al. 2020; Govarts et al. 2016; Sagiv et al. 2018; Starling et al. 2017; Wikstrom et al. 2020; Yao et al. 2021) (USEPA 2023a, p. 4-9). 2 of those were used for RfD determination because serum PFAS was measured in the first trimester (Sagiv et al. 2018; Wikstrom et al. 2020) (USEPA 2023a, p. 4-43). The agency also considered 6 high confidence studies of PFOS for POD development (Chu et al. 2020; Darrow et al. 2013; Sagiv et al. 2018; Starling et al. 2017; Wikstrom et al. 2020; Yao et al. 2021) (USEPA 2023b, p. 4-9), and the 2 that were used for RfD determination were the same as those chosen for PFOA (USEPA 2023b, p. 4-39).

For 5 of the studies, it is unknown if the study populations had clinically relevant changes in birth weights with PFOA or PFOS exposure (Sagiv et al. 2018; Starling et al. 2017; Wikstrom et al. 2020; Yao et al. 2021), because only mean or median birth weights were reported, none of

which were <2500 g. Among a Belgian birth cohort of 248 mother-infant pairs, the number of LBW infants was not reported, nor was the risk of LBW with PFOA or PFOS exposure examined, so it is unknown if there was an increased risk of an adverse effect in this population (Govarts et al. 2016).

The remaining 2 studies reported the risk of an LBW birth in the population. A study of the births among women in the C8 population of highly exposed individuals observed no significant associations between LBW births and PFOA or PFOS exposure (Darrow et al. 2013). In a study of 372 births in Guangzhou between July and October 2013 observed no significant associations between LBW and PFOA exposure. A statistically significant association was observed between LBW and PFOS (OR=2.43, 95% CI: 1.09-5.147), but not by quartiles of PFOS exposure. Authors also noted that the relationship between PFAS and birth outcomes was controversial due to concerns regarding effective dose, reverse causality, and sample timing. Based on the limited reporting on birth weights and inconsistent evidence of increased risk of LBW in the candidate studies, the evidence for an adverse effect with PFOA or PFOS exposure in that study is not clear.

EPA Response: The commenter incorrectly suggested that the EPA did not follow its own guidance while evaluating the impacts of exposure to PFOA or PFOS on changes to developmental health outcomes. The EPA disagrees and provides a detailed response on how these assessments applied the EPA peer-reviewed human health risk assessment methodology (USEPA, 2022a) in the EPA Response to 4.1.1 above. Responses to other specific criticisms are outlined below.

The commenter incorrectly stated the EPA did not follow its own guidance while concluding the evidence synthesis judgement for developmental health outcomes was *moderate*. First, the commenter is incorrect in calling the IRIS Handbook EPA guidance. It is not agency guidance but rather peer-reviewed human health risk assessment methodology. Though the IRIS handbook states that "[t]he handbook does not supersede existing U.S. Environmental Protection Agency (EPA) guidance and does not serve as guidance for other EPA programs," it does represent the state-of-the-art systematic review procedures and so the OW adhered to this peer-reviewed human health risk assessment methodology in developing the evidence synthesis judgement for the developmental health outcomes (USEPA, 2022a). The commenter outlines criteria for a *moderate* evidence synthesis judgement from the IRIS Handbook: "includes at least one high or medium confidence study reporting an association and additional information increasing certainty in the evidence. For multiple studies, there is primarily consistent evidence of an association with reasonable support for adversity, but there might be some uncertainty due to potential chance, bias, or confounding or because of the indirectness of some measures" ((USEPA, 2022a), Table 6-4)." The EPA disagrees that the evidence base for developmental effects, specifically decreases in BWT, does not align with the criteria for a *moderate* evidence synthesis judgement. For PFOA, deficits in mean BWT were observed in most studies (30/42) in the overall population. Additionally, 5 (Chang, 2022; Hjermitslev, 2020; Meng, 2018; Sagiv, 2018; Wikström, 2020) of 9 medium and high confidence studies reported evidence of reductions

in mean BWT based on early pregnancy biomarker samples. The majority of studies on changes in standardized BWT measures reported inverse associations (10/18), with most (7/10) of these being high and medium confidence studies which strengthens the confidence in this association. Similarly, most studies (12/17) observed either an increased risk of LBW or small for gestational age (GA) (see section 3.4.4.1 and 3.4.4.4.1 in USEPA, 2024d). For PFOS, deficits in mean BWT were observed in most studies (27/39) in the overall population. Additionally,5 (Bach, 2016; Hjermitslev, 2020; Meng, 2018; Sagiv, 2018; Wikström, 2020) of 8 medium and high confidence studies still reported evidence of mean BWT deficits based on early pregnancy biomarker samples. Most studies on changes in standardized BWT measures reported inverse associations (12/18) in the overall population or among boys or girls. Ten of 17 studies observed increased risk of LBW or small for gestational age (SGA) (see section 3.4.4.1 and 3.4.4.4.1 in USEPA, 2024c). The moderate evidence synthesis judgement for the developmental health outcome is further supported by consistency in other developmental effects. Specifically, for PFOS, increased risk of preterm birth was observed in 12 out of 17 studies (Section 3.4.4.4, USEPA, 2024c). These data clearly align with the IRIS evidence synthesis judgement criteria for *moderate*: "multiple studies [reporting] primarily consistent evidence of an association with reasonable support for adversity. *Moderate* evidence synthesis judgements may include "some uncertainty due to potential chance, bias, or confounding," and these issues have been outlined and discussed in detail in Sec. 3.4.4.4 (USEPA, 2023f; USEPA, 2023a). Further, supplemental evidence "may raise certainty in the evidence" base (USEPA, 2022a, Table 6-4), which included "several meta-analyses also support[ing] evidence of associations between maternal or cord blood serum PFOA and BWT or BWT-related measures {Johnson, 2014, 2851237; Verner, 2015, 3150627; Negri, 2017, 3981320; Steenland, 2018, 5079861}" (USEPA, 2023a, Sec. 3.4.4.4).

The commenter claimed studies observing non-significant increases in risk for SGA and LBW do not support the EPA's conclusion of *moderate* evidence for adverse developmental effects in humans, specifically reduced BWT. The EPA disagrees these studies do not support the EPA's *moderate* evidence synthesis judgement for developmental effects. Statistical significance is not the sole factor when making evidence synthesis judgements, and results that lack statistical significance can be used to support a conclusion of an effect (Wasserstein and Lazar, 2016; USEPA, 2022a). Despite non-significant findings, there was consistent evidence for PFOA and an increased risk of SGA or LBW in 12 out of 17 studies, and the "magnitude of the associations was typically from 1.2 to 2.8" (USEPA, 2023f; USEPA 2024d). Similarly for PFOS, 10 out of 18 studies reported non-significant "increased odds rang[ing] from 1.19 to 4.14" (USEPA, 2023a; USEPA 2024b). As mentioned above, these studies provide consistent evidence for effects in epidemiological studies that are coherent with LBW (i.e., SGA).

The commenter suggested evidence synthesis judgements should have been made for each unit of analysis within the developmental health outcome category. The EPA disagrees that evidence synthesis judgements are necessary for all unit of analyses and the EPA followed guidance outlined in the IRIS Handbook (USEPA, 2022a) as noted in the EPA Response above. First, the EPA states in the MCLG Appendix (A.1.10) that "strength-of-evidence judgments were made for each health outcome," which does not require a strength-of-evidence judgment for each

individual developmental endpoint (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b). IRIS human health risk assessment methodology states that multiple judgements for a health outcome category may be made, but this is a pre-determined decision, and considering the breadth of the endpoints examined in all included developmental studies the EPA chose to make one evidence integration summary judgement for all developmental health outcomes. Regardless of separate or combined evidence integration summary judgements, the ORD IRIS Handbook states that "the strongest evidence judgement will typically be used to reflect certainty in the broader health effect category," in the event of multiple evidence integration summary judgements for one health outcome category (USEPA, 2022a). Additionally, the EPA's approach to the summary judgment for the developmental health outcome is consistent with the evidence integration summary judgments for recent draft IRIS PFAS assessments (USEPA, 2023h, USEPA, 2023g, and USEPA, 2024g).

The commenter stated it is unknown whether the observed decreases in BWT associated with exposure to PFOA or PFOS from the studies used for POD derivation are clinically relevant or adverse. The EPA disagrees with this comment. Please see the EPA Response to 4.2.2.Derivation of the Noncancer Reference Doses (RfD) below. Additionally, as previous research on lead exposure has found, although on an individual-level, changes in BWT may or may not have fallen below 2,500 g, small changes in mean BWT can result in substantial health impacts at the population level (Gilbert and Weiss, 2006). BWT is a significant factor in infant survival (Jacob, 2016); several studies have reported relationships between BWT and mortality (Almond et al., 2005, Ma et al., 2020, McIntire et al., 1999; Lau et al., 2013).

Detailed responses to the specific uncertainties from developmental studies raised by the commenter are discussed in the EPA response to comment Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053428)

EPA's failure to conduct a transparent and consistent evaluation of the evidence base for developmental outcomes led to selection of candidate studies with critical limitations.

EPA (2023a,b) considered associations between PFOA and PFOS exposures and multiple developmental outcomes, including birth weight, birth length, head circumference, diagnosed condition of low birth weight,3 or small for gestational age,4 gestational duration, or diagnosed conditions such as preterm birth.5 EPA determined that there was moderate evidence of an association between PFOA or PFOS and developmental effects based on epidemiologic literature.

EPA did not appropriately consider uncertainties – most of which directly implicate bias in studies' results. These uncertainties include:

· Potential bias due to pregnancy hemodynamics and sample timing

· Potential confounding by other PFAS

· Mixed evidence for gestational duration, measured as gestational age or preterm birth

· Inconsistent evidence with rapid growth measures, including postnatal height and adiposity up to age 2

· Little evidence for increased fetal loss

· No evidence for increased birth defects

· Limited dose-response evidence in birth weight deficit studies

Additional details regarding the strength of evidence related to developmental outcomes are described in EPA Evidence Stream and Summary Judgments (EPA 2023a Table 3-10; EPA 2023b Table 3-12). The determination by EPA of a "moderate" level of evidence is not supported by the findings presented. In the appraisal of study quality and risk of bias, EPA did not evaluate studies consistently, which led to the selection of candidate studies for POD development with critical limitations. The evidence presented does not support PFOA and PFOS exposure and decreased birth weight as a critical endpoint.

Integration of developmental outcomes comprised inconsistent evidence.

As described above, EPA only provided evidence integration judgements for broad categories. EPA's determination of "moderate" evidence for developmental outcomes covers a broad category that includes specific categories such as birth weight, birth length, head circumference, LBW, SGA, gestational duration, fetal loss, post-natal growth, and birth defects (EPA 2023a Table 3-10; EPA 2-23b Table 3-12). EPA did not provide judgements for any one of these specific developmental outcomes separately, making it unclear how strong the evidence base was for each.

The underlying data across these types of effects do not support a categorization of "moderate" when properly evaluated according to EPA guidance and best practice. For example, in the summary of fetal growth restriction, EPA stated that the majority of studies that examined fetal growth restriction showed some evidence of associations with PFOA or PFOS. Head circumference and birth length were less consistent, with limited evidence of dose-response relationships. The agency concluded that, "despite some consistency in evidence across these fetal growth endpoints, some important uncertainties remain mainly around the degree that some of the results examined here may be influenced by sample timing. This source of uncertainty and potential explanation of different results across studies may indicate some bias due to the impact of pregnancy hemodynamics" (EPA 2023a p. 3-220; EPA 2023b p. 3-218).

EPA chose not to consider gestational duration outcomes for POD derivation including gestational age and preterm birth, stating "While overall there appears to be associations between PFOA/PFOS exposure and gestational duration, the inconsistencies in the database and lack of studies sampling in the first trimester of pregnancy reduce the level of confidence in the responses preferred for endpoints prioritized for dose-response modeling" (EPA 2023a,b). Fetal

loss and birth defects were also not considered as critical endpoints because of the limited number of studies available (EPA 2023a, p. 4-8; EPA 2023b, p. 4-8).

Given the lack of consistency in the scientific literature, it is unclear how EPA concluded that there is "moderate" evidence that PFOA/PFOS affect developmental outcomes. More specifically, this categorization is inconsistent with the criteria for an evidence synthesis judgement of "moderate" evidence in human studies.

EPA Response: The commenter incorrectly states the EPA did not adequately consider the following uncertainties while evaluating the evidence for developmental effects: potential bias related to pregnancy hemodynamics and exposure sample timing, potential confounding from PFAS co-exposures, mixed evidence for gestational duration, inconsistent evidence for postnatal growth, limited evidence for fetal loss and birth defects, and limited dose-response evidence for studies on BWT. Considerations of the uncertainties outlined above are described in each MCLG document (USEPA, 2023f; USEPA, 2023a, Sec. 3.4.4.1.2) and were discussed throughout the developmental synthesis (USEPA, 2023f; USEPA, 2023a, Sec. 3.4.4) and the discussion of study selection for developmental POD derivation (USEPA, 2023f; USEPA, 2023a, Sec 4.1.1.4). Specific considerations are described below.

Pregnancy hemodynamics were considered during study quality evaluation of developmental studies, with only *in utero* exposures being considered *Adequate* or better for Exposure Assessment (USEPA, 2023f; USEPA, 2023a, Sec. 3.4.4.1.2). Additionally, for studies on BWT, exposure sample timing was discussed in the results summaries. As described in the developmental synthesis, adverse effects on BWT were observed in studies with early pregnancy exposure samples. Additional studies with exposure samples from later pregnancy supported these findings. Although there are uncertainties related to pregnancy hemodynamics in the studies using later pregnancy samples, these uncertainties are not enough to explain the consistent effects observed across studies sampling in early and later pregnancy. In support of this, a recent meta-analysis for PFNA concluded that "deficits that were detected across all strata [i.e., early and later pregnancy] did not appear to be fully explained by potential bias due to pregnancy hemodynamics from sampling timing differences" (Wright et al., 2023). Given that there is no evidence that pregnancy hemodynamics would differ across PFAS, it is likewise unlikely that the decreases in birthweight observed for PFOA and PFOS can be fully attributable to pregnancy hemodynamics. Even so, further consideration of pregnancy hemodynamics and exposure sample timing occurred during study selection for quantitative analyses. Only *High* confidence studies utilizing early pregnancy exposure samples were considered for candidate RfD derivation (USEPA, 2023f; USEPA, 2023a, Sec. 4.1.5.4).

The EPA considered potential confounding by PFAS co-exposures during study quality evaluations and as part of the overall evidence stream judgment (USEPA, 2023f; USEPA, 2023a, Sec. 3.4.4.1.2 and Sec. 3.4.4.4). Further, the EPA has provided additional qualitative analysis examining the potential confounding by co-occurring PFAS (USEPA, 2024d; USEPA, 2024b, Sec. 5.1.1). This analysis supports the EPA's position that there is no consensus on best practices to account for potential confounding by multiple, concurrent PFAS exposures. Multi-pollutant

models may not perform as well when co-exposures are highly correlated, as is typical for PFAS mixtures. The degree of correlation between individual PFAS can lead to collinearity concerns, which may decrease precision. Multi-pollutant models may also lead to co-exposure amplification bias, where exposure measurement bias is amplified by the inclusion of multiple exposure terms with common but unaccounted for or unknown potential confounding. Other mixture analysis approaches, such as principal component analysis or elastic net regression, also have drawbacks, including difficulty interpreting effects for individual exposures and limited ability to examine non-linear associations. These challenges are also noted in the supplemental information to the *Toxicological Review of PFDA and Related Salts* (USEPA, 2023g, Sec. F.2), reflecting that analysis methods used to account for these co-exposures come with implementation challenges and introduce different uncertainties.

The EPA disagrees with the commenter's characterization of the evidence for gestational duration for PFOS. As outlined in the EPA response to comment Doc. #1774, SBC-05321, 8/10 high or medium confidence studies demonstrated a decrease in GA and 12/13 high or medium confidence studies demonstrated an increased risk of preterm birth. As described in 3.4.4.1.7.1 and 3.4.4.1.7.2, sample timing could not explain the consistency in the effects observed. This evidence helps to corroborate the observed decreases in birthweight (USEPA, 2023a; USEPA 2024b).

Regardless, and as stated above, positive associations or increased risk of adverse health outcomes (e.g., decreased birthweight) cannot be ignored, even if some inconsistency is present in the evidence base for other effects within the same health outcome (e.g., , inconsistent evidence of measures of postnatal growth). In fact, to do so would be in complete violation of agency human health risk assessment guidance (e.g., USEPA, 1991b) and the agency's peer-reviewed human health risk assessment methodologies (e.g., USEPA, 2002; USEPA, 2022a). Moreover, complete consistency within every health effect measured in a health outcome category is not necessarily an expectation of a body of observational studies in humans and does not necessarily result in a reduction in the overall confidence of this evidence stream. For example, for PFOA and PFOS, although multiple studies observed adverse effects on postnatal growth, thus supporting the evidence stream judgement, limitations in the evidence base for these endpoints included heterogeneity in outcome timing and characterization. Interpretation of effects observed across studies were difficult due to these limitations. The limited availability of directly comparable estimates for postnatal growth affected certainty of conclusions for these specific endpoints but did not impede the ability to draw conclusions for developmental effects overall. Likewise, a lack of evidence supporting an association between an agent and one endpoint (e.g., fetal loss, birth defects) does not necessarily influence the EPA's determination that there is an association between the agent and another endpoint (e.g., LBW) or influence the evidence stream judgment for that health outcome when there is abundant evidence supporting associations with other endpoints in that evidence stream, consistent with agency best practices (USEPA, 2022a).

Lastly, the EPA disagrees with the commenter's characterization of "limited dose-response evidence in birth weight deficit studies." As demonstrated in the forest plots of changes in mean BWT and odds of LBW, there was evidence of dose-response for BWT deficits (USEPA, 2023f; USEPA 2023a, Fig. 3-49–3-52 and Fig. 3-57). Categorical analyses of BWT generally reported linearly expressed associations, indicating BWT deficits with increasing exposure to PFOA or PFOS (USEPA, 2023f; USEPA, 2023a, Sec. 3.4.4.1.4.5). Due to the number of *high* and *medium* confidence studies observing BWT deficits with increasing exposure to PFOA (or PFOS), and in consideration with coherent adverse effects for other developmental outcomes (e.g., other measures of fetal growth restriction and gestational duration), BWT was chosen for dose-response analysis. This selection is consistent with the description of *moderate* evidence in human studies (USEPA, 2022a).

The commenter also states the EPA did not clearly communicate the strength of evidence for each developmental endpoint, limiting the transparency in the selection of a critical effect for POD derivation. The commenter suggests the evidence for fetal growth restriction does not support a categorization of *moderate* according to the methods provided by the EPA, specifically citing less consistent evidence for head circumference and birth length. The commenter disagrees with the *moderate* evidence integration judgment rating and cites as rationale the lack of consideration of gestational duration outcomes (e.g., preterm birth) as a critical effect. The EPA disagrees with these comments.

First, with respect to making evidence integration judgments for each developmental health outcome, see the EPA response to comment Doc. #1772, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document. Briefly, regardless of separate or combined evidence integration summary judgements, assessment methodology from the ORD IRIS Handbook states that "the strongest evidence judgement will typically be used to reflect certainty in the broader health effect category," in the event of multiple evidence integration summary judgements for one health outcome category (USEPA, 2022a).

Second, the EPA disagrees that inconsistencies between data for BWT and data for other fetal growth measurements undermine a *moderate* evidence integration judgement. The EPA describes considerations of potential inaccuracies or imprecision of fetal growth measurements in section 3.4.4.1.2 of the assessments (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). Briefly, numerous studies have demonstrated that some fetal growth restriction measurements, such as birth length (Shinwell and Shlomo, 2003; Johnson et al., 1998; Johnson et al., 1999; Wood et al., 2013) and head circumference (Bhushan and Paneth, 1991), are more subject to measurement error compared to measures such as birthweight. Therefore, birthweight is a more accurate and precise measure of fetal growth restriction and there were numerous *high* confidence studies that provided data that were able to be modeled.

Third, the EPA disagrees that it is necessary to consider gestational duration outcomes as a critical effect for POD derivation in order to conclude a *moderate* evidence stream judgment rating from studies in humans. As described above, the evidence in gestational duration outcomes is consistent and helps to corroborates the observed decreases in birthweight.

However, the evidence base for mean BWT contains more medium and high confidence studies which increases confidence in the birthweight endpoint for POD derivation (USEPA, 2024d; USEPA, 2024c). It is not necessarily an expectation that effects related to gestational duration would be equivalent to effects on birthweight, as the etiology of the outcome may differ, or be augmented by other unknown factors. It is also not the expectation that every endpoint considered within an evidence stream judgment have the same strength of evidence to be considered *robust* or *moderate*. A judgment of *moderate* for epidemiological evidence can result from a single or multiple adverse effects or a single or multiple well-conducted studies (USEPA, 2022a). In addition, uncertainty of an association between chemical exposure and a health effect resulting in the EPA's determination not to quantify the association does not necessarily mean the association is non-existent, nor does it automatically result in a decrease in the level of certainty supporting evidence of the hazard. For example, the commenter cited the EPA's rationale for not deriving PODs for the endpoint of gestational duration "While overall there appears to be associations between PFOA/PFOS exposure and gestational duration, the inconsistencies in the database and lack of studies sampling in the first trimester of pregnancy reduce the level of confidence in the responses preferred for endpoints prioritized for dose-response modeling." In context, the EPA was comparing this endpoint to the endpoint of LBW, which had a more consistent evidence base and several *high* confidence studies with sample collection during early pregnancy, which is ideal to avoid uncertainty due to hemodynamics. Therefore, the EPA focused modeling efforts on the endpoint of decreased birthweight, as there was higher confidence in the database for this effect. This interpretation of the database and resulting judgment designation are supported by protocols outlined in the *ORD Staff Handbook for Developing IRIS Assessments* (See Table 6-3; USEPA, 2022a). The EPA has added additional detail to Section 4.1.1. to enhance the transparency of endpoint selection (USEPA, 2024d; USEPA, 2024c).

Association of Metropolitan Water Agencies (AMWA) (Doc. #1738, SBC-046009)

Birthweight

Of the 32 studies that EPA used in its PFOA toxicity assessment, 21 reported some mean birthweight deficits in the overall population with limited evidence of exposure-response relationships [FN17: U.S. Environmental Protection Agency, "Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) in Drinking Water," March 2023, 3–205.]. Birthweight was found to have an inverse relation to PFOA concentration in a study of 293 infants at a mean PFOA concentration of 0.0016 micrograms per milliliters (µg/mL) [FN18: U.S. Environmental Protection Agency, 3–192.]. A 2012 study observed lower birthweights with increasing levels of maternal PFOA concentration (median concentration of 0.0037 µg/mL) [FN19: U.S. Environmental Protection Agency, 3–192; Mildred Maisonet et al., "Maternal Concentrations of Polyfluoroalkyl Compounds during Pregnancy and Fetal and Postnatal Growth in British Girls," Environmental Health Perspectives, 2012.].

Among the 21 studies showing some adverse associations in the overall population, there was a wide range of observed birthweight changes from –14 to –267 grams across both categorical and

continuous exposure estimates [FN20: U.S. Environmental Protection Agency, "2023b," 3–201.]. Among those with continuous PFOA results in the overall population, 14 of 20 studies reported deficits from –27 to –82 grams with increasing PFOA exposures. EPA notes, however, that there is limited evidence of exposure-response relationships and potential bias due to hemodynamic differences:

Three of the four smallest associations were based on earlier biomarker samples. Thus, some of these reported results may be related to pregnancy hemodynamic influences on the PFOA biomarkers during pregnancy. For example, 11 of the 12 largest mean BWT deficits (–48 grams or larger per unit change) in the overall population were detected among studies with either later pregnancy samples (i.e., maternal samples during trimesters 2, 3, or post-partum or umbilical cord samples) [FN21: U.S. Environmental Protection Agency, 3–201.].

EPA's caveat is important. Researchers have raised concerns with confounding and with possible reverse causation in studies taken late in pregnancy [FN22: Steenland, Kylea; Barry, Vaughna; Savitz, Davidb. Serum Perfluorooctanoic Acid and Birthweight: An Updated Meta-analysis With Bias Analysis. Epidemiology 29(6):p 765-776, November 2018. | DOI: 10.1097/EDE.0000000000000903]. Studies measuring concentrations in early pregnancy and prior to pregnancy do not show the same association.

For PFOS, one study found that birth weight, head circumference, and ponderal index were inversely associated with umbilical cord PFOS concentration in 293 infants [FN23: Benjamin Apelberg et al., "Cord Serum Concentrations of Perfluorooctane Sulfonate (PFOS) and Perfluorooctanoate (PFOA) in Relation to Weight and Size at Birth," Environmental Health Perspectives, 2007.]. Deficits in mean birth weight per one natural logarithm (ln) increase in PFOS concentration were found. Another study evaluated fetal growth outcomes in female births and found that increased maternal PFOS concentration (median concentration 0.0196 μg/mL) was associated with lower birth weights [FN24: Maisonet et al., "Maternal Concentrations of Polyfluoroalkyl Compounds during Pregnancy and Fetal and Postnatal Growth in British Girls."]. A prospective cohort study in Japan found that their "fully adjusted model showed no significant negative correlation between PFOA levels and birth weight. In contrast, a log10-unit increase in PFOS levels correlated with a decrease in mean birth weight of 148.8 g (95% CI, 297.0 to 0.5 g) for PFOS in the fully adjusted model." [FN25: Noriaki Washino et al., "Correlations between Prenatal Exposure to Perfluorinated Chemicals and Reduced Fetal Growth," Environmental Health Perspectives, 2009.] Another study examined 429 mother-infant pairs from the Taiwan Birth Panel Study and found that umbilical cord blood PFOS concentration was inversely associated with gestational age, birth weight, and head circumference [FN26: Mei-Huei Chen et al., "Perfluorinated Compounds in Umbilical Cord Blood and Adverse Birth Outcomes," PLOS One, 2012.].

However, studies conducted in Canada and Japan did not find a statistically significant association between birthweight and PFOS concentration in maternal blood [FN27: Michele Hamm et al., "Maternal Exposure to Perfluorinated Acids and Fetal Growth," Journal of Exposure Science and Environmental Epidemiology, 2010; Health Canada, "Guidelines for

Canadian Drinking Water Quality: Guideline Technical Document – Perfluorooctane Sulfonate (PFOS)," December 2018.]. Similarly, an examination of 429 mother-infant pairs from the Taiwan Birth Panel Study did not find a significant association between umbilical cord blood PFOS concentration and birthweight [FN28: Mei-Huei Chen et al., "The Impact of Prenatal Perfluoroalkyl Substances Exposure on Neonatal and Child Growth," Science of the Total Environment, 2017.].

A Canadian study of 252 pregnant women found no statistically significant association between birthweight or gestation length and PFOS concentration measured in maternal blood, although mean birthweight increased slightly by increasing PFOS levels [FN29: Hamm et al., "Maternal Exposure to Perfluorinated Acids and Fetal Growth."]. In its Health Effects Support Document, EPA notes that low confidence studies are included for consistency in the direction of association [FN30: U.S. Environmental Protection Agency, "2023b," 3–195.]. As shown in Appendix B, agencies have recognized additional limitations in study data, including selection bias, small study sizes, and confounding. This is also true of other adverse effects included in EPA's assessment.

Health Canada explains that "more studies with better adjustments and follow-up in different populations would be needed to confirm the observed associations." [FN31: Health Canada, "Guidelines for Canadian Drinking Water Quality: Guideline Technical Document – Perfluorooctanoic Acid (PFOA)," December 2018, 46.] Similarly, for certain effects, EFSA mentions that more studies are needed to support causality. Specific to birthweight, EFSA said that while "a recent study seems to strengthen the causality, the decrease in birth weight after adjusting for confounders is not large and the potential longer term consequences of this decrease are unclear." [FN32: Dieter Schrenk et al., "Risk to Human Health Related to the Presence of Perfluoroalkyl Substances in Food" (European Food Safety Authority, September 2020), 7.] A Department of Health and Human Services toxicological profile cited by WHO concluded that "no studies found increases in the risk of low birth-weight infants" associated with maternal PFOS serum levels." [FN33: Agency for Toxic Substances and Disease Registry, "Toxicological Profile for Perfluoroalkyls" (US Department of Health and Human Services, May 2021), 479; World Health Organization, "PFOS and PFOA in Drinking-Water: Background Document for Development of WHO Guidelines for Drinking-Water Quality," September 2022, 32, https://www.cmbg3.com/library/WHO-Draft-Drinking-Water-Document.pdf.]

EPA Response: Please see the EPA response to comment Doc. #1774, SBC—0053211 above in this *Response to Comments* document for the developmental hazard determination and the EPA response to comment Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document for a discussion of pregnancy hemodynamics. Please see EPA response to 4.2.6 Consideration of conclusions of other state, federal, or international agencies for details related to why the EPA's conclusions may differ from those of other international agency assessments. As discussed by the commenter, the majority of studies examining associations between elevated exposure to PFOA or PFOS and BWT reported inverse associations, indicating decreased BWT with greater exposure. The commenter then points to 4 studies which do not

show an association between PFOS and decreased BWT. The EPA considered over 40 studies in making the determination that PFOS is associated with decreased BWT. EPA acknowledged that there is potential uncertainty related to pregnancy hemodynamics, however the overall weight of evidence indicating decreased BWT with greater exposure, including in studies with sample timing in early pregnancy, resulted in an evidence synthesis judgement of *moderate* evidence for decreased BWT. Additionally, the EPA further considered pregnancy hemodynamics during candidate RfD determination. Specifically, of the six (five for PFOA) studies selected for PODHED derivation, the two (Sagiv, 2018; Wikstrom, 2020) measuring exposure concentrations from first trimester maternal blood samples were selected for candidate RfD derivation as described in Section 4 of the assessments (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c).

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053368)

Similarly, EPA's justification for relying on birthweight as a critical adverse effect is also not supported by science. Public commenters have noted that this endpoint is not an established causal effect of PFOA or PFOS exposure,[FN117: See comments submitted by Nessa Horewitch Coppinger on behalf of the 3M Company, Feb. 10, 2022, avahttps://sab.epa.gov/ords/sab/f?p=100:19:16404771425364:::RP,19:P19_ID:963.] but the revised documents ignore this concern. The SAB pointed out that the Wikstrom et al. 2020 study and the Sagiv et al. 2018 study, on which EPA relied for PFOA and PFOS birthweight endpoints, did not consider confounding by co- exposure to other PFAS (and realistically, other unmeasured chemicals and other stressors) [FN118: See SAB report to the EPA Administrator Aug. 22, 2022, at page 54, avahttps://sab.epa.gov/ords/sab/f?p=100:18:16490947993:::RP,18:P18_ID:2601#report.]. This omission would lead to an overestimate of the impacts of PFOA or PFOS on birthweight, yet it remains unaddressed in the Public Comment Draft Assessments or the Proposed Rule. Despite the SAB concerns, EPA considered these studies to be "high confidence" and does not address the concerns related to potential confounding.

EPA Response: Please see the EPA response to comment Doc. # 1774, SBC-053211 and Doc. # 1774, SBC-053428 in this *Response to Comments* document. Additionally, the EPA responded to SAB concerns regarding Wikstrom et al. (2020) in the *EPA Response to Final Science Advisory Board Recommendations (August 2022) on Four Draft Support Documents for the EPA's Proposed PFAS National Primary Drinking Water Regulation* document (Section I.E5A.2; USEPA, 2023e). Additional discussion of the EPA response to SAB concerns is available in section 4.1.2 of this *Response to Comments* document.

Mike Pettit (Doc. #1542, SBC-052841)

Developmental effects: pg 266 reads "Exposure to PFOA and PFOS during developmental life stages is linked to developmental effects including but not limited to the infant birth weight effects that EPA quantified. SGA is a developmental health outcome of interest when studying

potential effects of PFOA/PFOS exposure because SGA infants have increased health risks during pregnancy and delivery as well as post-delivery. Epidemiology evidence related to PFOA/PFOS exposure was mixed; some studies reported increased risk of SGA with PFOA/PFOS exposure, while other studies observed null results. For PFOS, few patterns were discernible, and overall confidence of an association between the two factors was low. Similarly, ATSDR found no strong associations between PFOA or PFOS exposure and increases in risk of SGA infants."

It is important to note that the mechanism of PFOS-induced developmental effects is not well understood. PFOS may affect developmental processes through several pathways, including disruption of hormone signaling, oxidative stress, and immune dysfunction. However, the precise mechanisms of action are still unclear, and this limits the ability to develop targeted interventions to mitigate the effects. Also of note is that there may be confounding factors that affect the association between PFOS exposure and developmental effects. For example, studies have shown that maternal stress during pregnancy can also affect fetal development, making it difficult to attribute developmental effects solely to PFOS exposure. Also of note, is that by the EPA's own admission (highlighted) is that the exposure effects are mixed, which again does not lend itself to any kind of gravity or even usefulness. As previously stated, there needs to be more consistent results- if there are mixed results then further investigation needs to be instituted. Statements, let alone laws, cannot use the weight of scientific evidence if it is mixed. If it is used, then it is used in the most incorrect and crooked way.

EPA Response: The commenter stated that the mechanisms of action by which PFOS induces developmental effects are unclear. The EPA agrees with this statement and directs readers to Section 3.4.4.3 of the PFOS toxicity assessment (USEPA, 2023a) which describes available mechanistic evidence supporting the effects of PFOS on development. The EPA additionally notes that mechanistic evidence is generally used to support the relevance of animal effects to humans and provide biological plausibility for evidence integration judgments but a definitive understanding of the mechanisms of action are not required for hazard identification or characterization (USEPA, 2022a).In fact, the IRIS handbook states that "if the mechanistic evidence is insufficient to provide a mechanistic or biological understanding of coherence (or lack thereof), this will not change the interpretation of the results from the human or animal studies (i.e., there is no increase or decrease in certainty)" (USEPA, 2022a).

The commenter additionally stated that there may be confounding factors such as maternal stress which make it difficult to attribute developmental effects solely to PFOS exposure. While the EPA agrees that confounding factors may influence study results when not controlled for appropriately through study design or statistical methods, the consistent evidence of developmental toxicity reported by animal toxicological studies mitigates these concerns. As stated in the PFOS toxicity assessment (USEPA, 2024b), "evidence based on 16 *high* or *medium* confidence animal studies indicates that the developing fetus is a target of PFOS toxicity. Dose-dependent maternal and offspring effects were reported in mice, rats, and rabbits." The highly controlled environments of animal toxicological studies limits the potential for confounding

factors to influence results, thus providing supporting evidence of the developmental effects reported in humans.

The commenter also claimed that the EPA stated the evidence for the developmental effects after PFOS exposure was "mixed." This is a mischaracterization of the EPA's conclusions, which were: "The evidence of an association between PFOS and developmental effects in humans is *moderate* based on the recent epidemiological literature." Though evidence for some individual endpoints within the developmental health outcome may have had mixed results (e.g., birth defects), evidence for fetal growth restriction, including LBW, was consistent. The EPA's conclusions regarding the developmental health outcome can be found in Section 3.4.4.4 of the PFOS toxicity assessment (USEPA, 2024b). The commenter also references ATSDR's SGA findings for PFOA and PFOS. Additional discussion of the EPA's consideration of assessment conclusions from other agencies is available in section 4.2.6 of this *Response to Comments* document.

Lastly, the commenter stated that a lack of knowledge about mechanisms of action "limits the ability to develop targeted interventions to mitigate the effects" of PFOS exposure. This is incorrect. Mitigation of effects results from the reduction or removal of contaminant exposure, which will be accomplished with implementation of the PFAS NPDWR.

4.2.1.3 Consideration of Increased Serum Lipids as a Critical Effect

3M Company (Doc. #1774, SBC-053281)

iii. EPA's assessment of cholesterol [FN77: EPA's conclusions regarding cardiovascular disease appear to be driven by its finding of an association between cardiovascular disease and cholesterol, which was the result of a flawed process, as discussed herein.] is inconsistent with best practice

EPA similarly did not adequately address the SAB request for transparency in its selection of outcome-specific studies for cardiovascular disease POD derivation. EPA acknowledges that the evidence for most cardiovascular-related endpoints such as changes in blood pressure, hypertension, coronary heart disease, and stroke is inconsistent (USEPA 2023a, b). Despite this limited evidence, however, EPA selects total cholesterol as the basis of the POD for cardiovascular effects. A complete and rigorous risk of bias assessment is needed to address underlying uncertainties and limitations in the available evidence base for changes in serum lipids, such as cholesterol. Contrary to SAB recommendations, the IRIS Handbook, and its own statements, for cardiovascular disease (CVD) outcomes, EPA failed to consider high-confidence and medium-confidence studies, including those that did not support an association between PFOA and PFOS exposure and CVD. EPA states that "only well-conducted high or medium confidence human and animal toxicological studies were considered for POD derivation, as recommended in the IRIS Handbook {U.S. EPA, 2022, 10476098}" (USEPA 2023a,b; p. 4-1). EPA's statement misleadingly suggests that it considered both high-confidence and medium confidence studies. In fact, EPA considered three studies for derivation of a cardiovascular POD

for PFOA and PFOS (Dong et al. 2019; Lin et al. 2019; Steenland et al. 2009); these three studies are all described as "medium-confidence" in the draft assessment (USEPA 2023a,b; p. 4- 7). However, EPA identified additional medium and high confidence studies but did not consider them for POD derivation.

Although EPA provides some information regarding evidence integration, the agency does not address the SAB's request for explanation of why a specific study was selected for POD derivation among multiple comparable choices for CVD outcome evaluation. Specifically, EPA does not explicitly describe why the high-confidence (Gardener et al. 2021; Li et al. 2021) and other medium-confidence studies (Averina et al. 2021; Christensen et al. 2019; Domazet et al. 2016; Donat-Vargas et al. 2019; Fan et al. 2020; Han et al. 2021; Jain and Ducatman 2018; Jain 2019; Kang et al. 2018; Kobayashi et al. 2022; Lin et al. 2009, 2019, 2020; Liu et al. 2018, 2020; Mora et al. 2018; Papadopoulou et al. 2021; Skuladottir et al. 2015; Spratlen et al. 2020; Tian et al. 2021; Zare Jeddi et al. 2021; Eriksen et al. 2013; Fisher et al. 2013; Geiger et al. 2014; Nelson et al. 2010; Sakr et al. 2007; Timmermann et al. 2014; Winquist and Steenland 2014) were not further considered for POD derivation.

Specific information on the selection criteria used by EPA to pare down the list of medium- and high-quality studies described in the Study Evaluations is necessary to provide confidence in the CVD POD derivation and toxicity assessment. Some studies not considered for POD derivation have study design components that may provide more confidence in the observed exposure-response relationships, including longitudinal designs or collection of multiple serum measurements (e.g., Donat-Vargas et al. 2019, Convertino et al. 2018). EPA did not provide justification and transparently describe the process used to select the three studies that were considered for dose-response evaluation (Dong et al., 2019; Lin et al. 2019; Steenland et al. 2009). Further, additional clarification on how to interpret "multiple judgments" within the findings of the study evaluation process is needed. For example, Steenland et al. (2009) was considered deficient (or "Low Confidence") in some EPA judgments (USEPA 2023a,b; see Figure 3-33), but EPA ultimately treated it as having adequate or "Medium Confidence."

Another deficiency that is contrary to the IRIS Handbook's guidance for study evaluation is EPA's inadequate control for confounding or correlated exposures (e.g., diet, family history, or co-exposure to other PFAS). EPA did not follow best practice as described in the IRIS handbook in that it heavily weighted studies that failed to consider confounding factors, such as family history and dietary factors, which are established contributors to CVD and serum lipids. However, none of the three studies considered by the USEPA for CVD POD derivation (Dong et al. 2019; Lin et al. 2019; Steenland et al. 2009) adjusted analyses to account for family history. Additionally, Dong et al. (2019) and Steenland et al. (2009) do not adjust for dietary habits or cholesterol intake. Intake of saturated fats, trans-fats, polyunsaturated fats, and monounsaturated fats are typically controlled for in randomized controlled trials evaluating impacts of cholesterol intake on TC, LDL-C and HDL-C, as intake is known to affect serum lipoprotein levels (Vincent et al. 2019; Allen et al. 2016; Mensink et al. 2003). Cholesterol intake has also been shown to affect serum lipoproteins (Vincent et al. 2019). Because of these relationships between dietary

patterns and circulating lipoproteins, the National Academies and USDA Dietary Guidelines recommend limiting trans and saturated fats and dietary cholesterol (while maintaining a healthy diet) as a major focus for reducing TC and LDL concentrations (USDA and HHS 2020). Lin et al. (2019) adjusted for "percent of daily calories from fat" and daily fiber intake from a "semiquantitative food frequency questionnaire with 177 items that measured dietary habits over the previous year." In their longitudinal analysis, Lin et al. (2019) found that associations between baseline PFAS and TC did not translate to an increased risk of hypercholesterolemia or hypertriglyceridemia in the lifestyle intervention group, indicating an effect of diet and exercise. Through use of poorly controlled cross-sectional analyses as the basis for RfD development, EPA failed to account for the effects of diet and exercise, well known contributors to CVD outcomes, in its assessment.

1. Contrary to EPA's best practices for systematic review and guidance, EPA did not evaluate study quality consistently for CVD

EPA did not transparently document risk of bias in each domain for each endpoint to ensure that the study quality evaluations are relevant to the endpoint being evaluated, as requested by the SAB. The SAB noted that: a protocol for risk of bias assessment and, more importantly, how that approach was used in the synthesis of evidence for each particular health endpoint is not clearly presented; and therefore, the results cannot be confidently evaluated for accuracy or transparency, or for consistency across health endpoints. This is especially important when a proposed systematic review protocol has not been previously registered or published. (USEPA SAB 2022, p. 6)

EPA's own best practices, as described in the IRIS Handbook, require that individual studies be evaluated for risk of bias and rated according to the Health Assessment Workplace Collaborative (HAWC) database. Here, EPA failed to comply with that guidance and best practice by failing to evaluate the risk of bias for each endpoint within a study that evaluated multiple endpoints. EPA presents Study Quality Evaluation results for each study with CVD outcomes, including serum lipid changes (see USEPA 2023a,b Figures 3-30 to 3-36). According to EPA, each study was evaluated for risk of bias using multiple study domains, including participant selection, exposure measurement, outcome ascertainment, confounding, analysis, selective reporting, and sensitivity. Results from each of these domains are synthesized into a characterization of the overall confidence in the individual study. Although individual studies were evaluated for risk of bias within each of these domains, review of the justifications supporting the risk of bias ratings provided in the HAWC database indicates that the risk of bias ratings for each domain are not necessarily determined relative to each individual endpoint considered in a study.

For example, EPA rated the domains for outcome ascertainment and results in Lin et al. (2019) as "Good" for serum lipids because "blood samples were collected at baseline, annual, and semi-annual follow-visits" (see USEPA 2023d for details). However, Lin et al. (2019) only collected PFOA and PFOS concentrations at baseline and the TC measurements considered as the basis for POD derivation were also collected only at baseline. Therefore, this rating is misleading for the

TC measurements considered by EPA if repeated measurements are part of the justification for a "Good" rating.

In another example, EPA rated the domains for participant selection, exposure measurement, outcome, and analysis in Gardener et al. (2021) as "Good," and these individual domain ratings contributed to the overall confidence categorization as a "High Confidence" study. However, as described within EPA's HAWC documentation, Gardener et al. (2021) is a pilot study that uses a non-nationally representative sample of pregnant women in the Vanguard Pilot Study of the National Children's Study. Although Gardener et al. (2021) evaluated serum lipid concentrations in pregnant women, the EPA's justifications regarding the quality of the outcome, confounding adjustments, and endpoint analysis specifically refer to the gestational age and birth weight endpoints only. Justifications for the confidence ratings of serum lipids as an endpoint in Gardener et al. (2021) are not provided in EPA's HAWC documentation.

By not properly conducting a systematic review and assessing studies for bias within individual endpoints, EPA did not correctly determine which endpoints were suitable for further evaluation. Thus, relevant endpoints and data may have been excluded or unreliable endpoints were included because EPA rated the study overall instead of refining its rating based on a specific endpoint of interest.

EPA Response: The EPA first directs the commenter to discussions related to the EPA response to SAB recommendations and to the EPA's adherence to appropriate guidance are available in Section 4.1.3 and Section 4.1.2, respectively.

In addition, the EPA disagrees with the commenter's characterization of evidence supporting the cardiovascular health outcome. The EPA selected total cholesterol as an outcome for POD derivation based on consistent evidence of serum lipids responses in humans following exposure to PFOA and PFOS, as well as coherent results for perturbations in lipid homeostasis in animal models (USEPA, 2023f; USEPA, 2023a, Table 3-8; Table 3-11). The absence of robust, high confidence evidence for other cardiovascular effects does not equate with an absence of association with PFOS or PFOA, nor does it negate the consistent findings for serum lipids (see the EPA response to comment Doc. # 1774, SBC-053429 in section 4.2.1.3 in this *Response to Comments* document). In situations where evidence for some outcomes was limited or of low confidence, the EPA relied on outcomes for which the evidence base was more robust.

The EPA evaluated risk of bias for all studies considered in the evidence integration for cardiovascular outcomes consistent with the protocols described in the IRIS Handbook (USEPA, 2023b; USEPA, 2023c, Sec. A.1.7). Results from this evaluation (referred to as "study quality evaluation") for studies examining serum lipids are available in section 3.4.3.1.2.2 of the PFOA/PFOS assessments, with additional details available in HAWC. Study quality evaluations were taken into consideration in the evidence integration process. This comment is further addressed later in this response.

The EPA also disagrees with the statements that it did not consider all *high* and *medium* confidence studies for POD derivation and that it did not provide a rationale for ultimately

selecting Dong et al. (2019), Lin et al. (2019), and Steenland et al. (2009) for quantitative assessments. The EPA outlined the criteria for selecting studies for POD derivation in Appendix A, Section A.1.11.1 (USEPA, 2023b; USEPA, 2023c). These criteria include a preference for *high* or *medium* confidence studies over *low* confidence studies, suitability of the data for modeling and relevance of exposure levels, among other factors. Therefore, while all *high* and *medium* confidence studies examining total cholesterol were considered as possible inputs to POD derivation, three studies (Dong et al. 2019, Lin et al. 2019, and Steenland et al. 2009) were ultimately selected as best suited for POD derivation based on all criteria considered together. To further enhance transparency of critical study selection, the EPA has added additional detail in section 2 (methods) to explain that medium and high confidence studies which supported the evidence integration judgement were considered for POD derivation (USEPA, 2024d; USEPA, 2024c). Additionally, explicit rationale as to why other medium and high-quality studies demonstrating an association between PFOA or PFOS exposure and increased total cholesterol were not selected has been added to section 4.1.1.3 of the toxicity assessments (USEPA, 2024d; USEPA, 2024c).

With respect to the Donat-Vargas et al. (2019) study, though this study was rated as *medium* confidence, it was not selected for POD derivation because it was the only medium quality study, out of 19 for PFOA and 17 for PFOS, to report an inverse association between serum cholesterol and PFOA or PFOS levels. Because this study provided results which were inconsistent with the majority of the other general population TC studies, it was not considered for dose response analysis. Additionally, Donat-Vargas et al. (2019)had a smaller sample size (n = 187) than the studies selected for POD derivation (Dong et al., 2019 (n = 8,849); Lin et al., 2019 (n = 940); Steenland et al., 2009 (n = 46,494). Convertino et al. (2018) was rated as *low* confidence due to lack of consideration for potential confounding in the statistical analysis and was not considered for POD derivation as outlined in the methods section 2.2 and section 4.1 of the assessments (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c).

Regarding the multiple confidence ratings reported for Steenland et al. (2009), this study included multiple outcomes of varying quality; thus, study confidence ratings were outcome-specific consist with the IRIS handbook (USEPA, 2022a) and as detailed in HAWC study evaluation (https://hawc.epa.gov/rob/study/101163917/). The rating of *low* confidence for overall study confidence pertains only to the test guideline (TG) and LDL-C outcomes. The TC outcome in Steenland et al. (2009), which was used as the basis for POD derivation, was rated *medium* confidence for overall study quality. This issue is further discussed in the EPA response to comment Doc. #1774, SBC-053429 in section 4.2.1.3 in this *Response to Comments* document.

Additionally, the EPA disagrees that the studies selected for cardiovascular POD derivation did not adequately address potential confounding. The EPA evaluated all studies for bias due to potential confounding during study quality evaluation (USEPA, 2023b; USEPA, 2023c, Table A-21). As described in Table A-21 (USEPA, 2023b; USEPA, 2023c), only studies in which the potential impact of residual confounding by such factors is judged to be minimal receive a rating of "adequate" for this evaluation domain. Regarding specific risk factors noted by the

commenter, confounding may occur only when a variable is associated with both the exposure and the outcome of interest. As such, while variables such as family history may be risk factors for TC, they would also need to be associated with PFOA or PFOS exposure in order to act as a confounder. The commenter provides no data to support this association. Additionally, regarding the issue of potential confounding by exercise, all three studies selected for POD derivation evaluated potential confounding by physical activity; thus, the claim that the EPA did not account for exercise is inaccurate. This issue is further discussed in the EPA response comment Doc. #1774, SBC-053429 in section 4.2.1.3 in this *Response to Comments* document.

The commenter provided additional concerns regarding the EPA's evaluation of the risk of bias for each individual endpoint within studies that included multiple health outcomes, which they characterized as a recommendation made by the SAB. The commenter based this statement on evaluations available in HAWC for two cardiovascular studies (Lin et al., 2019; Gardener et al., 2021). Regarding Lin et al. (2019), the commenter stated that the rating of "Good" in the outcome ascertainment domain for serum lipids was misleading, as only baseline TC measurements were considered in the analysis. Regarding Gardener et al. (2021), the commenter stated that the text in HAWC for the outcome, confounding, and analysis domains discussed GA and BWT but not serum lipids.

First, the EPA disagrees that individual health outcomes within a single study were not considered in study quality evaluation. As further discussed in the EPA response to comment Doc. #1774, SBC-053429 in section 4.2.1.3 in this *Response to Comments* document, the EPA provided information on how individual health outcomes were considered in Appendix A, Tables A-20 and A-24 of the assessments (USEPA, 2023f; USEPA, 2023a). Specifically, reviewers created multiple evaluations under the outcome ascertainment domain and multiple judgments for the overall confidence rating**,** if needed, to capture different health outcomes. In many cases, multiple judgments were not needed as the confidence across multiple endpoints was the same. All studies were independently evaluated using this protocol by two primary reviewers. A quality assurance reviewer resolved any conflicts and made final rating determinations, consistent with the IRIS Handbook (USEPA, 2022a).

Second, the EPA disagrees that the "Good" rating for serum lipids in the outcome domain of the study quality evaluation for Lin et al. (2019) is not appropriate. Under this domain, reviewers evaluate the extent to which the outcome measure(s) "reliably distinguish the presence or absence (or degree of severity) of the outcome" (Appendix A, Table A-20; USEPA, 2023f; USEPA, 2023a). As such, the justification for the "Good" rating in this domain is appropriately based on the methods used to measure serum lipids (e.g., laboratory methods), rather than timing of the outcome measurement relative to the exposure measurement. Furthermore, information regarding the choice to use data from Lin et al. (2019) on the cross-sectional association between baseline PFAS and baseline TC for POD derivation is provided in Appendix E, section 1.3.3 (USEPA, 2023f; USEPA, 2023a). While Lin et al. (2019) additionally included longitudinal analyses of the relationship between baseline PFAS and incident hypercholesterolemia and

hypertriglyceridemia, results were presented in the placebo and lifestyle intervention groups separately, thus limiting their use in POD derivation.

Third, regarding Gardner et al. (2021), although the main goal of the study was to evaluate developmental outcomes, the commenter expresses concern that cardiovascular outcomes were not originally described in the Outcome Ascertainment domain for study quality evaluation, though they were presented in the study evaluation heat maps and HAWC. Therefore, to ensure full completeness and transparency, the EPA has provided outcome-specific ratings in the Outcome Ascertainment domain for total cholesterol and triglycerides in the study quality evaluation for Gardener et al. (2021) (https://hawc.epa.gov/rob/study/101164025/).

Finally, the commenter mischaracterizes the SAB PFAS panel's quoted recommendations. In the quote provided by the commenter, the SAB suggested the EPA provide additional information on the risk of bias assessment process and its use in evidence synthesis, not that the EPA create independent evaluations for each health outcome within a study. In response to this guidance from SAB, the EPA added information on the relevant protocol in Section 2 of the toxicity assessments, as well as in the Appendices (USEPA, 2023f; USEPA, 2023a); this information was previously discussed in the EPA response to SAB comments document (USEPA, 2023d).

3M Company (Doc. #1774, SBC-053429)

EPA's failure to conduct a transparent and consistent evaluation of the evidence base for cardiovascular outcomes led to selection of candidate studies with critical limitations.

In its appraisal of study quality and risk of bias related to cardiovascular disease (CVD), EPA did not evaluate studies consistently, which led to the selection of candidate studies for POD development with critical limitations.6 EPA (2023a,b) determined that there is moderate evidence from the epidemiological literature for a relationship between PFOA and PFOS and serum lipids changes, with uncertainties stemming broadly from:

· Inconsistencies in TC results for PFOA in adults by sex and health status

· Mixed findings of significant increases in and no association with TC and HDL for PFOS

· Mixed findings of increases and decreases in TG associated with PFOS

· Mixed evidence for LDL for PFOA and PFOS

· Inverse associations for HDL and TG with PFOA in occupational populations, and

· Mixed evidence in children

The determination by EPA that there is a "moderate" level of evidence that PFOS/PFOA exposure are related to cardiovascular disease was made via a flawed process that rendered EPA's conclusion unreliable.

EPA did not transparently integrate evidence for cardiovascular outcomes.

EPA did not develop independent evidence stream judgments for each of the CVD effects identified as critical. EPA also did not transparently integrate animal and human information, or discuss the relative weight of each specific endpoint (e.g., serum lipids, hypertension, CVD, and atherosclerotic changes) considered in the Evidence Stream Judgment and the Evidence Integration Summary Judgments (EPA 2023a, Table 3-8, p. 3- 184 to 3-189; EPA 2023b, Table 3-11, pp. 3-176 to 3-182). EPA did not discuss its confidence in using risk factors for CVD effects, such as TC or LDL, in the absence of clear evidence of CVD outcomes. Accordingly, the public cannot meaningfully comment on whether EPA's treatment of animal information and weight accorded to each specific endpoint represents sound scientific methodology.

Despite failing to use transparent evidence judgments to evaluate these CVD outcomes, EPA confidently states 1) that there is no consistent evidence for associations between PFOA or PFOS and increased blood pressure in the general adult population, and 2) that "evidence for other CVD-related outcomes was more limited, and similarly inconsistent." (EPA 2023a p. 3-154; EPA 2023b p. 3-144). EPA states there is also no consistent evidence for associations between CVD-related outcomes or blood pressure in children, either. EPA stated that "Overall, the limited evidence available among children and adolescents was inconsistent and indicates PFOS is not associated with blood pressure in these age groups. The evidence for an association between PFOS and other CVD-related endpoints assessed in this study population was limited and inconsistent" (EPA 2023b, p. 3-140 to 3-141).7

Despite the admitted uncertain evidence for a relationship between PFOA and PFOS exposures and CVD outcomes, EPA selected changes in serum lipids as a critical endpoint for POD derivation. However, changes in serum lipids are not necessarily adverse on their own. The inconsistency and absence of strong evidence for observed CVD outcomes weakens confidence in the use of serum lipid changes as a critical effect (see Section 2.3.2). They are therefore not a valid critical endpoint for POD derivation.

EPA did not evaluate evidence regarding changes in serum lipids consistent with SAB recommendations.

EPA did not carefully consider the magnitude of the impact of PFOA and PFAS exposures and whether the changes in serum lipid measurements are clinically relevant. The SAB commented, "It is important to clearly demonstrate that the endpoints selected for POD development are well established, sensitive, adverse or precursor to adverse, and that endpoints from animal studies are relevant to humans" (EPA 2023c p. 20). Changes in serum lipids can be affected by many lifestyle and hereditary factors and there is a broad range of serum lipid measurements that are considered "normal." Therefore, best practice was for EPA to have accounted for such lifestyle and hereditary factors when using a risk factor or potential precursor of CVD for setting the POD, especially in the absence of clear CVD effects.

For example, Dong et al. (2019), the key study used for serum lipids POD derivation by EPA, calculated an estimate of 0.4 mg/dL (95% CI 0.06-0.6) increase in TC per 1 ng/mL PFOS and an estimate of 1.48 mg/dL (95% CI 0.2-2.8) increase in TC per 1 ng/mL PFOA. This suggests that

increases in serum TC associated with PFOA or PFOS exposures may not correspond to levels that are considered elevated (e.g., ≥ 240 mg/dL) per standard clinical practice and the American Heart Association's definition of hypercholesterolemia (NCHS 2019). As stated in Dong et al. (2019)'s discussion of study limitations, "the clinical significance of the elevated cholesterol levels was not investigated, which may inhibit the BMD/BMDL application in regulations [emphasis added]".

Although EPA used dose-response information from individual studies (Steenland et al. 2009; Dong et al. 2019; Lin et al. 2019) for POD derivation, EPA presents a meta-analysis, with sensitivity analyses evaluating inclusion and exclusion of low confidence studies, as part of the Economic Analysis for the proposed MCLs (see EPA, 2021b; Analysis of Cardiovascular Disease (CVD) Risk Reduction as a Result of Reduced PFOA and PFOS Exposure in Drinking Water). In that meta-analysis, EPA reports that "For PFOA, when all the studies were combined, EPA observed nonsignificant positive increases in TC of 0.003 (95% CI: −0.001, 0.006) mg/dL per ng/mL serum PFOA (p-value = 0.177, I2 = 89%) and for HDLC of 0.001 (95% CI: −0.001, 0.004) mg/dL per ng/mL serum PFOA (pvalue = 0.291, I2 = 71%). When the low-confidence studies were excluded, the results for both TC and HDLC were similar to the associations observed when all the studies were included in the meta-analysis, with 0.003 (95% CI: −0.003, 0.008) for TC (p-value = 0.321, I2 = 89%), and 0.002 (95% CI: −0.002, 0.005) for HDLC (p-value = 0.290, I2 = 58%)." (EPA 2023c p. 74, see Economic Analysis Appendix F, Table F-2 p. F-11). Nonsignificant increases in TC (p = 0.055) and HDLC (p = 0.631) were reported for PFOS when all studies were included (see Economic Analysis Appendix F, Table F-3 p. F-17). However, "when the analysis excluded the four higher ROB [risk of bias] studies, the association was significantly positive for TC (0.086, (5% CI: 0.001, 0.17, p-value = 0.047, I2 = 100%) and remained the same for HDLC (0.001, 95% CI: −0.001, 0.002, p-value = 0.606, I2 = 83%)" (EPA 2023c p. 74).

Given the lack of consistency in CVD outcomes, lack of evidence that serum lipid changes result in adverse CVD outcomes, and the lack of evidence that observed increases in serum lipids are clinically adverse, EPA needs to provide additional consideration of the clinical relevance of the serum lipid changes to justify selection of increased TC as a critical endpoint for POD development. Otherwise, its analytical process is fundamentally flawed.

EPA did not synthesize evidence in accordance with SAB recommendations or Agency Guidance; candidate study selection was not transparent and therefore PODs may have been derived without consideration of the full body of evidence.

To select endpoints for POD development, the SAB commented, "Internal inconsistencies in the criteria used for selection of endpoints for POD development should be addressed. It is also important to explain why a specific study of a health endpoint was selected when there are several possible choices." For CVD outcomes, EPA states that "only wellconducted high or medium confidence human and animal toxicological studies were considered for POD derivation, as recommended in the IRIS Handbook {U.S. EPA, 2022, 10476098}" (EPA 2023a,b; p. 4-1). Three studies were considered by the EPA for derivation of a POD for PFOA and PFOS

(Dong et al. 2019; Lin et al. 2019; Steenland et al. 2009); these three studies are described as "medium-confidence" in the draft assessment (EPA 2023a,b; p.4-7). However, EPA identified additional medium and high confidence studies but they were not considered by EPA for POD derivation.

EPA has not addressed the SAB's request for explanation of why specific studies were selected for POD derivation among multiple comparable choices for CVD outcome evaluation. Specifically, EPA does not explain why the high-confidence (Gardener et al. 2021; Li et al. 2021) and other medium-confidence studies (Averina et al. 2021; Christensen et al. 2019; Domazet et al. 2016; Donat-Vargas et al. 2019; Fan et al. 2020; Han et al. 2021; Jain and Ducatman 2018; Jain 2019; Kang et al. 2018; Kobayashi et al. 2022; Lin et al. 2009, 2019, 2020; Liu et al. 2018, 2020; Mora et al. 2018; Papadopoulou et al. 2021; Skuladottir et al. 2015; Spratlen et al. 2020; Tian et al. 2021; Jeddi et al. 2021; Eriksen et al. 2013; Fisher et al. 2013; Geiger et al. 2014; Nelson et al. 2010; Sakr et al. 2007; Timmermann et al. 2014; Winquist and Steenland 2014) were not further considered for POD derivation. These studies provide valuable information to the agency and represent some of the best available science on POD derivation in this context.

Some studies not considered for POD derivation have study design components that may provide more confidence in the observed exposure-response relationships, including longitudinal designs or collection of multiple serum measurements (e.g., Donat-Vargas et al. 2019 or Convertino et al. 2018). EPA did not transparently describe the process used to select the three studies that were ultimately considered for dose-response evaluation (Dong et al., 2019; Lin et al. 2019; Steenland et al. 2009). Additionally, EPA relied on one study, Steenland et al. (2009), that was considered deficient (or "Low Confidence") in some judgments (EPA 2023a,b; see Figure 3-33). Steenland et al. (2009) should not be considered as adequate or "Medium Confidence." Relatedly, EPA needs to clarify the meaning of "multiple judgments" within the findings of the study evaluation process. Specific information on the selection criteria used by EPA to pare down the list of mediumand high-quality studies described in the Study Evaluations is necessary to provide confidence in the POD derivation and toxicity assessment.

Transparency in the approaches used by EPA during incremental steps, such as evaluating and categorizing overall study confidence through a formal risk of bias assessment, is imperative for understanding the uncertainties in the ultimate toxicity assessment. If EPA had appropriately conducted a formal risk of bias assessment, the three studies the agency selected as candidates for POD derivation would have been found deficient or critically deficient and would have not been deemed acceptable for selection as candidate studies. Each of the three studies EPA considered (Dong et al. 2019; Steenland et al. 2009; Lin et al. 2019) were cross-sectional in nature, and the longitudinal components of Lin et al. (2019) were not evaluated. As noted by Dong et al. (2019), "The NHANES data are capable of examining the association but cannot address the issue of causality. Similar to other cross-sectional studies, this study cannot answer whether: 1) exposure to PFASs elevates the cholesterol level; 2) high cholesterol levels allow the storage of PFASs easier; or 3) joint factors simultaneously affect both PFASs and cholesterol" (p. 466). Steenland et al. (2009) notes that "Interpretation of these data is made difficult by our

cross-sectional design, which prohibits knowing whether an increase in cholesterol followed an increase in PFOA or PFOS." Therefore, use of these three studies for derivation of a POD is limited due to the nature of the study design, alone.

Other critical deficiencies that likely would have precluded the selected studies from consideration include inadequate control for confounding or correlated exposures (e.g., diet, family history, or co-exposure to other PFAS). Family history and dietary factors are established contributors to CVD and serum lipids. However, none of the three studies considered by EPA for POD derivation (Dong et al. 2019; Lin et al. 2019; Steenland et al. 2009) adjusted analyses to account for family history. Additionally, Dong et al. (2019) and Steenland et al. (2009) do not adjust for dietary habits or cholesterol intake. Intake of saturated fats, trans-fats, polyunsaturated fats, and monounsaturated fats are typically controlled for in randomized controlled trials evaluating impacts of cholesterol intake on TC, LDL-C and HDL-C, as intake is known to affect serum lipoprotein levels (Vincent et al. 2019; Allen et al. 2016; Mensink et al. 2003). Cholesterol intake has also been shown to affect serum lipoproteins (Vincent et al. 2019). Therefore, it is critical that a study consider the impact of diet and dietary factors on serum lipoproteins in each analysis.

Other critical considerations are the timing of serum lipid measurements. In the population assessed by Steenland et al. (2009), fasting blood samples were not consistently collected, and so a variable was added to the analysis to account for fasting in the 6 hours prior to blood sampling.8 Differences in fasting and non-fasting lipid samples will unnecessarily increase heterogeneity and uncertainty in the underlying outcome samples.

In summary, EPA did not adequately address the SAB request for transparency in its selection of outcome-specific studies for POD derivation, especiall,y when there are numerous studies to choose from. A complete and rigorous risk of bias assessment is needed to address underlying uncertainties and limitations in the available evidence base for changes in serum lipids.

EPA did not evaluate study quality consistently for CVD outcomes, in contrast to best practices in systematic review and guidance.

EPA presents Study Quality Evaluation results for each study with CVD outcomes, including serum lipid changes (see EPA 2023a,b Figures 3-30 to 3-36). According to EPA, each study is evaluated for risk of bias using multiple study domains, including participant selection, exposure measurement, outcome ascertainment, confounding, analysis, selective reporting, and sensitivity. Results from each of these domains are synthesized into a characterization of the overall confidence in the individual study.

As part of this process, the agency evaluated individual studies for risk of bias within each domain. The justifications supporting EPA's risk of bias ratings were provided in the Health Assessment Workplace Collaborative (HAWC) database. Those justifications indicate that the risk of bias ratings for each domain are not necessarily determined relative to each individual endpoint considered in a study. For example, EPA rated the domains for outcome ascertainment and results in Lin et al. (2019) as "Good" for serum lipids because "blood samples were

collected at baseline, annual, and semi-annual follow-visits" (see EPA 2023d for details). However, Lin et al. (2019) only collected PFOA and PFOS concentrations at baseline and the TC measurements considered as the basis for POD derivation were also collected only at baseline. Therefore, this rating is misleading for the TC measurements considered by EPA if repeated measurements are part of the justification for a "Good" rating.

In another example, EPA rated the domains for participant selection, exposure measurement, outcome, and analysis in Gardener et al. (2021) as "Good", and these individual domain ratings contributed to the overall confidence categorization as a "High Confidence" study. However, Gardener et al. (2021) is a pilot study that uses a nonnationally representative sample of pregnant women in the Vanguard Pilot Study of the National Children's Study. Although Gardener et al. (2021) evaluated serum lipid concentrations in pregnant women, EPA's justifications regarding the quality of the outcome, confounding adjustments, and endpoint analysis specifically refer to the gestational age and birth weight endpoints only. EPA did not provide justifications for the confidence ratings of serum lipids as an endpoint in Gardener et al. (2021) in the HAWC documentation.

Based on these examples of flawed reporting within HAWC, it is not clear that EPA evaluated the risk of bias for individual endpoints within each study, as recommended by the SAB. EPA did not transparently document risk of bias in each domain for each endpoint to ensure that the study quality evaluations are relevant to the endpoint being evaluated. Without such documentation, the public cannot have confidence that the agency properly evaluated each study for its quality with respect to each endpoint. This renders EPA's entire analysis suspect, and stands in stark contrast with fundamental principles of scientific integrity.

EPA Response: The commenter is directed to section 4.1.1 of the EPA response in this *Response to Comments* document for concerns about the systematic review process used. systematic review protocol for PFOA and PFOS assessments. The commenter suggested the EPA did not adequately address SAB recommendations or follow appropriate guidance for study evaluation. Discussions related to the EPA response to SAB recommendations and to the EPA's adherence to appropriate guidance are available in sections 4.1.3 and 4.1.2 of this *Response to Comments* document.

The commenter additionally stated that the EPA did not evaluate studies related to CVD risk consistently and raised concerns over inconsistencies in the evidence for PFOA and TC by sex and health status among adults, mixed evidence for associations between PFOS and several types of serum lipids (TC, High-Density Lipoprotein [HDL], and TG), mixed evidence for associations between both PFOS and PFOA and Low-Density Lipoprotein (LDL), inverse associations for PFOA and several types of serum lipids (HDL and TG) in occupational populations, and mixed evidence in children.

First, the EPA disagrees that it did not evaluate studies of CVD consistently. The EPA evaluated all studies following the protocol described in Appendix A, section A.1.7 (USEPA, 2023f; USEPA, 2023a). All studies were independently evaluated using this protocol by two primary

reviewers. A quality assurance reviewer resolved any conflicts and made final rating determinations, consistent with the IRIS Handbook (USEPA, 2022a) and the *Systematic Review Protocol for the PFAS IRIS Assessments* (USEPA, 2021a).

Second, as stated in the EPA response to comment Doc. #1774, SBC-053429 in section 4.2.1.3 in this *Response to Comments* document, complete consistency within a health outcome category is not an expectation of a body of observational studies in humans and does not necessarily result in a reduction in the overall confidence of an evidence stream. For example, variation in associations between PFOA and TC by sex within studies (e.g., Jain and Ducatman, 2019b, as summarized in Section 3.4.3.1.2.5 of the PFOA assessment (USEPA, 2023f) could reflect differing susceptibility between men and women. Variation in results by health status across studies, as was observed in Lin et al. 2019, Liu et al. 2020, and Donat-Vargas et al. 2019(PFOA assessment, Section 3.4.3.1.2.5 (USEPA, 2023f)), may similarly reflect differing susceptibility or could have arisen from differences in study methods. Regardless, the available evidence indicates an association between PFOA and increased TC, with 15 of 13 of 15 medium confidence studies in the general adult population reporting positive associations (USEPA, 2024d, Section 3.4.34).

Third, the EPA disagrees with the commenter's characterization of the evidence for PFOS and TC. Among adults, 13 of the 15 medium confidence studies reported evidence of a positive association between PFOS and TC (PFOS assessment (USEPA, 2024c), Section 3.4.3.4). Regarding associations between PFOS and both HDL and TG, the EPA agrees with the commenter's statement that findings were mixed (see PFOS assessment (USEPA, 2023a), Section 3.4.3.4). However, the evidence for TC and LDL was the main driver for the EPA's determination of moderate evidence for an association between PFOS and cardiovascular effects in humans. Lack of evidence supporting an association between an agent and one endpoint (e.g., TG) does not necessarily influence the evidence stream judgment for that health outcome when there is abundant evidence supporting associations with other endpoints in that evidence stream. Additionally, in the case of TG, serum levels are more subject to outcome misclassification than other serum lipid endpoints, such as TC, due to the potential effect of fasting on measurements, potentially contributing to heterogeneous results. This was explicitly noted as an outcome-specific factor that the EPA considered during study quality evaluation (Section 3.4.3; USEPA, 2023f; USEPA, 2023a).

Fourth, the EPA disagrees with the commenter's characterization of the evidence for LDL and both PFOS and PFOA. Among adults, the evidence supports positive associations with LDL (USEPA, 2024d Table 3-8; USEPA, 2024c Table 3-11). Specifically, in general population adults included in the public comment draft (USEPA, 2023f; USEPA, 2023a), 6 out of the 8 medium confidence studies reported positive associations between LDL concentrations and elevated PFOA, and 9 out of 11 medium confidence studies reported similar positive associations for PFOS (USEPA, 2024d; USEPA, 2024c). In addition to these studies, studies examining serum lipids identified after the 2022 updated literature search also reported evidence of increased serum LDL concentrations with elevated PFOA and PFOS (Appendix A.3; USEPA, 2024a;

USEPA, 2024b). These consistent findings are supportive of the moderate evidence stream judgment for the cardiovascular health outcome.

Fifth, the occupational studies measuring serum lipids and PFOA exposure are largely low confidence studies so the ability to draw conclusions in this population is limited (Section 3.4.3.4.1, USEPA, 2024d; USEPA, 2024c). Nevertheless, 8 out of the 10 occupational studies demonstrate a consistent association between PFOA exposure and increased TC (7/8) or increased risk of high cholesterol (1/2). Next, 4 of the 7 occupational studies that measured TG reported an increased association, though 6 put of those 7 studies were low quality for TG. The occupational studies that examined associations between PFOA and HDL were more mixed and mostly low quality. Considering human studies of PFOA and serum lipids as a whole, particularly the consistent associations between PFOA and increased serum lipids in the general adult population in higher confidence studies, the EPA's determination of moderate evidence is warranted.

Finally, regarding mixed evidence in children, expected changes in serum lipids during early childhood present methodological challenges for studying associations in this age group. Specifically, in the first two years, serum lipid concentrations tend to increase until they reach puberty, and then serum lipid levels subsequently decrease during puberty (Daniels et al., 2008). This age- and maturation-dependent fluctuation in serum lipids leads to difficulty in comparing results between different age groups in childhood. As such, the EPA based its determination of moderate evidence for an association between serum lipids and cardiovascular outcomes in humans primarily on studies conducted in adults (USEPA, 2024d Table 3-8; USEPA, 2024c Table 3-11). The EPA has added this rationale to the Serum Lipids Introduction (Section 3.4.3.1.2.1) and Study and Endpoint Selection for Cardiovascular effects (Section 4.1.1.3) (USEPA, 2024d; USEPA, 2024c).

The EPA emphasizes that the evidence stream judgment is for all **cardiovascular outcomes** (which includes CVD) and not specifically for CVD only, as the commenter incorrectly states. Overall, the evidence from epidemiological studies, particularly *medium* and *high* confidence studies conducted in adults from the general population and reporting LDL and TC, support a moderate judgment for this evidence stream.

The commenter additionally stated that the EPA did not develop an evidence stream judgment for each CVD endpoint, nor did the EPA describe how evidence for different endpoints was synthesized to arrive at Evidence Stream and Evidence Integration Summary Judgements. The commenter stated that the EPA did not provide a transparent description of its approach for integrating animal and human evidence. The commenter stated that the EPA did not provide a justification for using CVD risk factors (i.e., serum lipids) in POD derivation in the "absence of clear evidence" of effects on CVD endpoints and further states that serum lipids should not be used for POD derivation for this reason. The commenter also cited inconsistent or limited evidence for associations with blood pressure in the general adult population and other CVD-related outcomes as rationale for reduced confidence in the EPA's determination to use changes in serum lipids as a critical effect, as well as inconsistent evidence for associations with blood

pressure among children. The EPA disagrees with these statements and addresses each in detail below.

First, the EPA followed the evidence synthesis and integration approach in Appendix A (p. A-139 PFOS, A-116 PFOA) to arrive at a judgment for cardiovascular outcomes as a whole (USEPA, 2023f, USEPA, 2023a). The commenter appears to incorrectly conflate conclusions the EPA makes regarding studies of CVD and CVD-related outcomes in specific populations with the EPA's overall conclusions on the association between PFOA or PFOS and cardiovascular effects. The approach outlined in Appendix A does not require a strength-of-evidence judgment for each individual cardiovascular endpoint, nor does it require consistency across every study, population, or effect. Rather, this approach is based on the IRIS handbook which states that multiple, more granular evidence integration judgements can be made for a health outcome if the data allow, but this is generally a pre-determined decision based on manifestations of potential toxicity (e.g., creating separate judgements for immunosuppression and allergic response) (USEPA, 2023f). However, as stated previously, this is not a requirement of the IRIS Handbook evidence integration framework (USEPA, 2022a). The cardiovascular studies included in these two assessments examined a large breadth of related cardiovascular endpoints without clear, pre-determined differences in potential toxicity, and, as a result, the evidence integration judgement was made for the larger cardiovascular health outcome category. Cardiovascular endpoints with higher quality studies (and a larger quantity) drove conclusions for forming strength-of-evidence judgments. Judgments on endpoints with low quality or limited evidence may obscure coherent effects for endpoints within the same health outcome category with higher quality evidence. Regardless of separate or combined evidence integration summary judgements, guidance from the IRIS Handbook states that "the strongest evidence judgement will typically be used to reflect certainty in the broader health effect category," in the event of multiple evidence integration summary judgements for one health outcome category (USEPA, 2022a).

Second, the EPA describes how data from animal and human evidence streams were integrated in Table A-41 (USEPA, 2023f; USEPA, 2023a; USEPA, 2023f). In reference to the judgment rendered for cardiovascular outcomes, the table states that a judgment of *evidence indicates (likely)* is warranted in situations "with moderate human evidence supporting an effect and slight or indeterminate animal evidence, or with moderate animal evidence supporting an effect and slight or indeterminate human evidence." This judgment is appropriate given the moderate evidence for effects in both humans and animals (USEPA, 2023f, Table 3-8; USEPA, 2023a, Table 3-11). The EPA further described how the evidence from animal toxicological studies supports evidence from human studies in Section 4.1.1.3 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c).

Finally, the EPA disagrees that serum lipids are not a valid endpoint for POD derivation. While studies included in this assessment examined a range of CVD outcomes, evidence for most individual outcomes was limited as described in section 3.4.3.4 (USEPA, 2024d; USEPA, 2024c; USEPA, 2023f; USEPA 2023a). When evidence for some outcomes was very limited or of low quality (e.g., risk of stroke or hypertension in occupational studies), the EPA relied on outcomes

for which the evidence base was more robust (e.g., serum TC in adults). The absence of robust, high-quality evidence does not equate with an absence of association for these endpoints, nor does it negate the consistent findings for serum lipids. The consistent findings for serum lipids are also supported by evidence of associations with blood pressure in adult populations in *high* and *medium* confidence studies as was summarized in Tables 3-8 and 3-11 of the draft PFOA and PFOS toxicity assessments, respectively (USEPA, 2023f; USEPA, 2023a). While the commenter correctly pointed out that associations with blood pressure among children are inconsistent, this lack of consistency does not negate the consistent findings among the general adult population. Furthermore, it is not the expectation that every endpoint considered within an evidence stream judgment have the same strength of evidence for the overall determination to be considered robust or moderate. A judgment of *moderate* confidence for epidemiological evidence can result from a single or multiple adverse effects or a single or multiple well-conducted studies (USEPA, 2022a). In addition, uncertainty of an association between chemical exposure and a health effect resulting in the EPA's determination not to quantify the association does not necessarily mean the association is non-existent, nor does it automatically result in a decrease in the level of certainty supporting evidence of the hazard.

The EPA disagrees with the commenter's assertion that changes in serum lipid concentrations associated with PFOS or PFOA are not clinically relevant. Such serum lipid changes may or may not result in a concentration considered clinically elevated in a particular individual, however, given the distribution of individual concentrations within the population, small changes in average serum lipid concentrations can result in substantial health impacts at the population level (Gilbert and Weiss, 2006). For example, studies have shown that increases in lipid levels is one of the most important risk factors for CVD after menopause (Carr, 2000; El Khoudary, 2020). Similarly, the SAB PFAS Panel commented on this exact concern and stated that "[f]or the four most consistent endpoints [decreased antibody response, increased TC, increased ALT and decreased birthweight], most studies report relatively small changes in clinical biomarkers. While most of these studies did not evaluate the number of subjects with a clinically abnormal value for biomarkers, one or more studies, for each of the four effects, reported an association of PFOA and/or PFOS with increased risk of a clinically abnormal value…In studies where the number of subjects with clinically abnormal values was not specifically evaluated, an increase in the number of subjects with a clinically abnormal value is also expected from the overall change (shift in the distribution curve) in the abnormal direction. While the clinical relevance of exposure to PFOA or PFAS cannot be predicted on an individual basis, **the increased number of individuals within a population with clinically defined abnormal values is of public health concern"** (emphasis added) (USEPA, 2022b). To be responsive to public comments, the EPA has added discussion on this issue in Section 4.1.1.3 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c).

As described in the EPA response to comment Doc. #1774, SBC-053281 in section 4.2.1.3 in this *Response to Comments* document, the EPA evaluated potential confounders that could plausibly be associated with both PFOS/PFOA and health outcomes in humans (e.g., lifestyle) during study quality evaluation (Appendix A, Table A-21, USEPA, 2023f; USEPA, 2023a; USEPA 2024d;

USEPA 2024c)). As described in the table, only studies with minimal potential impact from residual confounding by such factors received a rating of "adequate" for this evaluation domain. Therefore, the EPA does account for "lifestyle and hereditary factors when using a risk factor or potential precursor of CVD for setting the POD," as the commenter recommended. Importantly, confounding may occur only when a variable is associated with both the exposure and the outcome of interest (USEPA, 2022a). As such, while variables such as family history may be risk factors for increased total cholesterol, they would also need to be associated with PFOA or PFOS exposure in order to act as a confounder. There is currently no evidence to support that family history of CVD impacts PFOA and PFOS exposure and the commenter does not provide any evidence to support this association.

Finally, the selection of TC as an endpoint for POD development is well-justified considering the potential for substantial population-level health impacts described above and the consistent evidence of adverse associations with serum lipids. As outlined in the EPA response to comment Doc. #1774, SBC-053281 in section 4.2.1.3 in this *Response to Comments* document, while evidence was limited for most CVD outcomes other than serum lipids, the absence of a robust evidence base for these outcomes does not equate with an absence of association, and, as such, does not negate the consistent findings for serum lipids. The SAB also stated, "elevated serum cholesterol is one of the better-established effects of PFAS exposure in humans," supporting the EPA's selection of serum total cholesterol as an endpoint for POD derivation (USEPA, 2022b).

The commenter stated that the EPA did not provide a rationale for the selection of three studies (Dong et al. 2019, Lin et al. 2019, Steenland et al. 2009) for POD derivation among other high and medium confidence studies. The commenter stated that Steenland et al. (2009) should not be considered a medium confidence study due to "deficient" ratings in some study quality evaluation domains. The commenter requested that the EPA clarify the meaning of "multiple judgments exist" within the study quality evaluation process. The commenter stated that the EPA did not conduct a formal risk of bias assessment for the studies selected for POD derivation and that such a formal assessment would have resulted in deficient ratings due to study design considerations. The commenter stated that the three studies selected for POD derivation did not account for family history (Dong et al. 2019, Lin et al. 2019, Steenland et al. 2009) and/or dietary habits or cholesterol intake (Dong et al. 2019, Steenland et al. 2009) and further states that these limitations should likely have precluded the three studies from further consideration. The commenter stated that fasting blood samples were not consistently collected in Steenland et al. (2009) and asserts that this lack of consistency may increase uncertainty in the measured outcomes. The EPA disagrees with these statements and detailed responses to each point below.

First, the EPA provided information on the process for selecting studies for POD derivation in Appendix A, Section A.1.11.1 (USEPA, 2023f; USEPA, 2023a). The criteria for selecting studies for POD derivation are related to, but distinct from, the study quality evaluation process. For example, studies that were rated high or medium confidence in study quality evaluation are preferred for POD derivation, but other factors, such as suitability for modeling and data availability (e.g., categorical exposure levels), are also considered. However, the EPA has added

explicit rationale for why these three medium studies were selected while other medium confidence studies were not to sections 4.1.1 of the final toxicity assessments (USEPA, 2024d; USEPA, 2024c). This rationale is provided below to address the studies listed by the commenter.

Importantly, for a study to be considered for POD derivation, the study must support the evidence integration judgement for cardiovascular outcomes. Therefore, the 4 medium quality studies which reported an inverse (Donat-Vargas et al. 2019) or null association (Fisher, 2013; Liu, 2020; Han, 2021) for serum lipids were not considered for POD derivation. The EPA determined that the overall evidence indicated an association between increased serum lipids and PFOA exposure and that this association was most evident in the general population as outlined earlier in this response (USEPA, 2024d, Section 3.4.3.4). Therefore medium quality studies in other subpopulations such as, pregnant women (Skuladottir et al. 2015; Gardener et al. 2021), occupationally exposed workers (Sakr et al. 2007; Winquist and Steenland 2014) and children (Li et al. 2021; Jain and Ducatman 2018; Averina et al. 2021; Domazet et al. 2016; Kang et al. 2018; Mora et al. 2018; Kobayashi et al. 2022; Lin et al. 2009; Papadopoulou et al. 2021; Spratlen et al. 2020; Geiger et al. 2014; Timmermann et al. 2014; Tian et al. 2021) were not further considered. Studies in pregnant women were limited, but 3 out of the 4 available studies show a positive association between TC and PFOA exposure, supporting the findings in the general population. Similarly, 7 out of 8 occupational studies reported positive associations between TC and PFOA exposure, supporting the findings in the general population, however the majority of these studies were low quality. As mentioned above, expected changes in serum lipids during early childhood present methodological challenges for studying associations in this age group (Daniels et al., 2008) therefore, EPA based its determination of moderate evidence for an association between serum lipids and cardiovascular outcomes in humans primarily on studies conducted in adults.

Four general population adult studies presented overlapping data from NHANES (Nelson, 2010; Liu, 2018; Fan, 2020; Dong, 2019). Of these four, Dong et al. (2019) was selected for POD derivation because the study included all NHANES cycles between 2003 and 2014, while the other three studies reported results for one or two cycles only and were therefore excluded. Similarly, two studies (Fitz-Simon, 2013; Steenland, 2009) presented data on the C8 Health Project population. Fitz-Simon et al. (2013) was excluded from POD derivation because it was a part of the short-term follow-up and was not as comprehensive as the population examined by Steenland et al. (2009). Therefore, Steenland et al. (2009) was also selected for POD derivation. Finally, Lin et al. (2019) was selected for POD derivation and represented adults from the Diabetes Prevention Program (DPP) population.

Other general adult population studies listed by the commenter were not selected for a variety of reasons. Two studies cited by the commenter (Eriksen, 2013; Lin, 2020) were excluded from POD derivation due to narrow age ranges (i.e., 50–65 years of age, 55–75 years of age, and 20–39 years of age, respectively) of the study populations that were less comprehensive than the age groups included by other studies and therefore, may not apply across the general adult population. One study {Jain and Ducatman, 2019b) was excluded from POD derivation because

the study reported findings stratified by BMI status without stratification by exposure Finally, the other studies listed by the commenter did not report TC measurements (Christensen et al. 2019; Li et al. 2021; Jeddi et al., 2021).

Second, the EPA disagrees that Steenland et al. (2009) should not be considered a *medium* confidence study. Steenland et al. (2009) was rated "deficient" in the outcome ascertainment domain and was rated "low" for overall study confidence only for the TG and LDLC outcomes. The other serum lipids in this analysis, including TC, which was used for POD derivation, were rated "adequate" in the outcome ascertainment domain and "medium" for overall study confidence (https://hawc.epa.gov/study/101163917/). A "low" study confidence rating for one endpoint does not necessarily reduce confidence for other endpoints reported in the same study.

Third, the EPA provided multiple judgments for studies when they included multiple health outcomes and reviewers judged that the different outcomes merited different ratings (Appendix A, Tables A-20 and A-24). This approach is outlined in the IRIS Handbook (USEPA, 2022a, Sec. 4.1 and 4.2.2) and was described at the beginning of each health outcome section as studies with *mixed* confidence ratings. The EPA used the language of *mixed* ratings for priority health outcomes (USEPA, 2023, Sec. 3.4.1, 3.4.2, 3.4.3, and 3.4.4) and multiple judgements for non-priority health outcomes (USEPA, 2023, Appendix C) in the public comment draft. The language for all health outcome sections has been clarified to *mixed* ratings.

Fourth, the EPA disagrees that a formal risk of bias assessment was not conducted for the studies selected for POD derivation and further disagrees that the design of these studies limits their use in this process. The EPA evaluated all studies consistently, including risk of bias, with the protocols described in the IRIS Handbook (Appendix A, section A.1.7). As part of this process, reviewers considered the timing of exposure measurement relative to the outcome within the specific context of each study (Appendix A, Tables A-18 and A-19). However, cross-sectional design alone does not justify rating a study deficient. Furthermore, the EPA reiterates that the process for selecting studies for POD derivation (Appendix A, Section A.1.11.1) is distinct from the process used to evaluate risk of bias and that cross-sectional design does not prevent selection of a study's for this purpose.

Fifth, the EPA disagrees that the use of the three studies selected for POD derivation is limited by their considerations of confounding. Reviewers evaluated the potential for confounding-related bias in each study by considering the approaches used to both identify and control for potential confounders (Appendix A, Table A-21). Not all risk factors for the outcome are considered confounders; rather, a risk factor must also be associated with exposure to be considered a confounder. As such, risk factors such as family history are unlikely to confound the association between PFOS/PFOA and serum lipids and the reviewer has not provided any references supporting an association between family history and PFOS/PFOA levels. Regarding cholesterol intake and dietary habits, the commenter notes and provides evidence that these factors "are typically controlled for in randomized controlled trials." The studies provided by the commenter relied on controlled trials only, specifically excluding observational studies (Vincent et al., 2019; Allen et al., 2016). The studies included in these meta-analyses controlled for dietary intake by

placing participants on specified, controlled diets. This approach is vastly different from controlling for dietary habits in statistical analyses through covariate adjustment, as the commenter is suggesting should have been done in Steenland et al. (2009) and Dong et al. (2019). The latter approach may be subject to recall bias and participants would be expected to have considerable differences in dietary intake of cholesterol or fatty acids as they are not on controlled diets. Additionally, the studies concluded that cholesterol intake was associated with changes in LDL-C, and specifically notes that the impact on HDL-C was less clear (Vincent et al., 2019). The evidence base consisted primarily of observational epidemiology studies which have risk-of-bias considerations distinct from controlled human exposure studies (USEPA, 2022a). For example, the IRIS Handbook suggests incorporation of aspects from other tools such as the Cochrane RoB tool for randomized trials (RoB 2) or the ROBINS-I tool when evaluating controlled human exposure studies (USEPA, 2022a).

Lastly, the EPA disagrees that the lack of fasting blood samples in Steenland et al. (2009) decreases confidence in the results. The EPA consistently rated the Outcome Ascertainment domain for studies without consideration of fasting status. Analyses of TC and HDL-C were not downgraded for lack of consideration of fasting status, however, due to susceptibility to postprandial effects, analyses of TG and LDL-C (which is commonly derived using TG) were downgraded if fasting status was not addressed. As the commenter points out, Steenland et al. conducted an analysis for triglycerides in which fasting status was included in regression models. Steenland et al. report that the inclusion of this variable in the analysis of TG resulted in differences, but for other serum lipid outcomes (e.g., TC) this had little impact on the results, strengthening confidence in the results for these outcomes. Furthermore, in a sensitivity analysis stratified by fasting status, Steenland et al. observed similar trends in both fasters and non-fasters. Therefore, the EPA maintains the confidence determination for Steenland et al. (2009) and continues to use this as a critical study to derive candidate RfDs for the endpoint of serum total cholesterol. For completeness and transparency, details on the sensitivity analyses for serum lipids has been added to the study quality evaluation for Steenland et al. (2009).

The commenter stated that the EPA did not consistently evaluate individual health outcomes assessed in a given study for risk of bias, which they characterize as a recommendation made by the SAB. The commenter based this statement on study quality evaluation data from HAWC for two cardiovascular studies (Lin et al. 2019, Gardener et al. 2021). Regarding Lin et al. 2019, the commenter states that the rating of "Good" for serum lipids in the outcome ascertainment domain is misleading, as only baseline TC measurements were considered in the analysis. Regarding Gardener et al. 2021, the commenter states that the text for the outcome, confounding, and analysis domains discuss GA and BWT but not serum lipids.

First, the EPA disagrees that individual health outcomes within a single study were not consistently evaluated in study quality evaluation. The EPA provides information on how individual health outcomes were considered in Appendix A, Tables A-20 and A-24. Specifically, if multiple judgments were needed to capture different health outcomes, reviewers created multiple evaluations under the outcome ascertainment domain and multiple judgments for the

overall confidence rating. All studies were independently evaluated using this protocol by two primary reviewers, and a quality assurance reviewer resolved conflicts and made final rating determinations, consistent with the IRIS Handbook (Appendix A, section A.1.7).

Second, the EPA disagrees that the "Good" rating in the outcome domain of the study quality evaluation for Lin et al. 2019 is not appropriate for serum lipids. Under this domain, reviewers evaluate the extent to which the outcome measure(s) "reliably distinguish the presence or absence (or degree of severity) of the outcome" (Appendix A, Table A-20). As such, the justification for the "Good" rating in this domain is appropriately based on the methods used to measure serum lipids (e.g., laboratory methods), rather than timing of the outcome measurement relative to the exposure measurement. Furthermore, information is provided in Appendix E, section 1.3.3 regarding the choice to use data on the cross-sectional association between baseline PFAS and baseline TC from Lin et al. (2019) in POD derivation. While Lin et al. (2019) additionally included longitudinal analyses of the relationship between baseline PFAS and incident hypercholesterolemia and hypertriglyceridemia, results were presented in the placebo and lifestyle intervention groups separately, thus limiting their use in POD derivation.

Third, regarding Gardener et al. 2021, although the main goal of the study was to evaluate developmental outcomes, the EPA recognizes the commenter's concern that cardiovascular outcomes were not originally described in the text, though they were presented in the study evaluation heat maps and HAWC. Therefore, for completeness and transparency, the EPA updated the text of Section 3.4.3.1.2.4 to describe confidence ratings and study results for the serum lipid outcome described in Gardener et al. (2021).

Finally, the commenter mischaracterizes the SAB's recommendation. In reference to this point, the commenter included a quote from the Study Evaluation section on page 6 of the SAB's final report (see the SAB's response to Charge Question #1; USEPA, 2022b): "a protocol for risk of bias assessment and, more importantly, how that approach was used in the synthesis of evidence for each particular health endpoint is not clearly presented; and therefore, the results cannot be confidently evaluated for accuracy or transparency, or for consistency across health endpoints." (USEPA, 2022b, page 6). In this quote, SAB is suggesting that the EPA provide additional information on the risk of bias assessment process and its use in evidence synthesis, not that the EPA create independent evaluations for each health outcome within a study. In response to this guidance from SAB, the EPA added information on the relevant protocol in Section 2 of the draft toxicity assessments as well as in the Appendices (USEPA, 2023f; USEPA, 2023a; USEPA, 2023b; USEPA, 2023c).

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053367)

Consideration of clinical relevance is also important when evaluating EPA's reliance on cholesterol as a marker of cardiovascular disease. In commenting on the Dong et al. 2019 study, which EPA relied upon for PFOA and PFOS, the SAB could not discern why this study was chosen, stated that EPA's lack of information on the study did not appear to support its use, and

strongly recommended that EPA consider older studies [FN112: See SAB report to the EPA Administrator Aug. 22, 2022, at page 18, avahttps://sab.epa.gov/ords/sab/f?p=100:18:16490947993:::RP,18:P18_ID:2601#report.]. However, in the proposed rule, EPA continues to rely on the Dong et al. 2019 study. Importantly, the SAB notes that the epidemiologic literature that provides strong support for an effect of PFAS on cholesterol does not provide support for an effect of PFAS on the risk of cardiovascular disease [FN113: Id. at 102.]. Similarly, as pointed out by Steenland et al. 2020, in evaluating the C8 Science Panel data, while an association between PFOA and elevated cholesterol is plausible, there is no impact on the risk of cardiovascular disease [FN114: Steenland K, Fletcher T, Stein CR, Bartell SM, Darrow L, Lopez-Espinosa M-J, Ryan PB, Savitz DA. (2020) Review: Evolution of Evidence on PFOA and Health Following the Assessments of the C8 Science Panel, Environment International, Volume 145, 106125.]. In fact, the Proposed Rule states "EPA recognizes that the epidemiologic literature that provides strong support for an effect of PFOA and PFOS on cholesterol and blood pressure does not provide direct support for an effect of PFOA and PFOS on the risk of cardiovascular disease (CVD)." [FN115: 88 Fed. Reg at 18709.] Statements like these call into question why EPA continues to rely on this endpoint as a critical effect. In fact, additional recent studies continue to disprove any human CVD disease endpoint (such as stroke, myocardial infarction, or other measurable CVD), and highlight the overreach in attributing CVD to PFOA or PFOS [FN116: Schillemans T, Donat-Vargas C, Lindh CH, de Faire U, Wolk A, Leander K, et al. (2022) Per- and polyfluoroalkyl substances and risk of myocardial infarction and stroke: a nested case-control study in Sweden. Environ Health Perspect130(3):37007, available at: https://ehp.niehs.nih.gov/doi/10.1289/EHP9791.].

EPA Response: Regarding the use of the Dong et al. (2019) study for POD derivation, the EPA addressed all of the SAB's concerns related to selecting this study for POD derivation prior to releasing the draft toxicity assessments for public comment (USEPA, 2023f; USEPA, 2023a; USEPA, 2023d). First, the EPA provided rationale for why this particular study was chosen in section 4.1 of the assessments. The EPA also provided additional modeling details in Appendix E of the assessments in order to detail the modeling that was performed by EPA how the EPA used additional information provided by the study authors to perform hybrid modeling for this study (USEPA, 2023b; USEPA, 2023c). Additionally, the EPA did select multiple studies for POD derivation, including studies) that were published in the 2016 HESDs ((i.e., Steenland et al., 2009) for PFOA and PFOS, as recommended by the SAB. Finally, the EPA has added additional reasons for why other medium quality studies were not selected for POD derivation sections 4.1.1.3 of the toxicity assessments (USEPA, 2024d; USEPA, 2024c).

Importantly, the commenter mischaracterizes the SAB's support of the link between increased cholesterol and CVD. The SAB "support[ed] the overall approach to estimating reductions in cardiovascular disease (CVD) risk associated with reductions in exposure to PFOA and PFOS in drinking water" (USEPA, 2022b). Additionally, the SAB also supported the use of all four noncancer endpoints quantified in the draft, including increased cholesterol because "[i]n studies where the number of subjects with clinically abnormal values was not specifically evaluated, an increase in the number of subjects with a clinically abnormal value is also expected from the

overall change (shift in the distribution curve) in the abnormal direction. While the clinical relevance of exposure to PFOA or PFAS cannot be predicted on an individual basis, the increased number of individuals within a population with clinically defined abnormal values is of public health concern" (USEPA, 2022b).

Regarding the clinical relevance of the cholesterol endpoint, please see section 4.2.2 of the EPA response in this *Response to Comments* document, as well as the EPA response to comment Doc. #1774, SBC-053429 in section 4.2.1.3 in section 4.2.1.3 in this *Response to Comments* document. The latter response additionally describes the EPA's process for critical study selection, which was more transparently described in the PFOA and PFOS toxicity assessments as a result of the SAB comments described by the commenter (USEPA, 2022b; USEPA, 2023d). Please see the EPA response to comment Doc. #1841, SBC-044832 in section 4.2.1.1 in this *Response to Comments* document for a response to Schillemans et al. (2022).

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053370)

1. EPA's evidence integration approach is flawed

EPA's approach and presentation of its evidence integration findings is flawed and does not represent the best available science or the best available scientific approach to evaluating evidence. For instance, for PFOS, as discussed in the Public Comment Draft Assessment, the 2016 HESD assessment did not assess evidence for associations between CVD diseases and PFOS, besides the review of its effects on serum lipids. Since the 2016 HESD, EPA identifies 45 new epidemiological studies that report on the association between PFOS and "cardiovascular disease" (with endpoints widely ranging from outcomes such as hypertension [in 19 of 45 new studies], CVD, congestive heart failure, microvascular diseases, to mortality). EPA determined that 4 of these studies were high confidence and 23 were medium confidence [FN120: Id. At 3-136.]. EPA has misplaced its emphasis on quantity of "CVD" studies rather than considering the underlying endpoint relevance when determining if in fact any of the endpoints are scientifically attributable to the action of PFOS (via MOA discussion) given the numerous confounders present in every study cited. EPA then concludes, "Overall, the findings from a single high confidence study and several medium confidence studies conducted among the general population provided consistent evidence for an association between PFOS and blood pressure." [FN121: Id. At 3-144.] The concern here is that EPA is not discussing the weight of evidence of all the studies evaluated but is instead drawing its conclusion on the positive studies only. It is clear that there are also medium quality studies that do not show any association, but EPA appears to ignore them when reaching its weight of evidence conclusion.

EPA does not array these data in tabular form, as one would present in a meta-analysis, which would make it easier for readers to discern how EPA is integrating the evidence. EPA's apparent approach of relying on just a few of the positive studies is a not a scientifically sound approach. This is but one example; EPA follows this similar structure and framework for the majority of the non-cancer endpoints assessed in the Public Comment Draft Assessments. EPA has not

sufficiently addressed the SAB concerns and has not provided a transparent and reproducible framework for evaluating the evidence.

EPA Response: The commenter's inadequately supported claim that the "EPA's approach and presentation of its evidence integration findings is flawed and does not represent the best available science or the best available scientific approach to evaluating evidence" shows a lack of understanding about the systematic review that the EPA performed and what constitutes best available science. Please see sections 4.1.1 1, 4.1.2, and 4.1.3 of the EPA response in this *Response to Comments* document. The commenter is also pointed to section 4.2.1 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-053211 and Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document regarding the EPA's consideration of all studies reporting cardiovascular effects, including serum lipids, while synthesizing and integrating evidence for the cardiovascular health outcome.

With respect to blood pressure, the commenter does not provide any evidence to support their claim that the EPA ignored medium confidence studies in determining that "[o]verall, the findings from a single high confidence study and several medium confidence studies conducted among the general population provided consistent evidence for an association between PFOS and blood pressure" (USEPA, 2023a). In fact, studies examining changes in blood pressure, including DBP and SBP, and risk of hypertension in general population adults showed consistent positive associations with increased risk of hypertension (4/7), positive associations for SBP (7/9) and DBP (7/8), including four medium or high confidence studies reporting significant increases (4/6) (Section 3.4.3.4, USEPA, 2024c).

The commenter incorrectly stated that the EPA did not array data on cardiovascular effects in a tabular form which makes it difficult for readers to understand how the EPA integrated the evidence. The EPA disagrees that the evidence is not presented clearly. The EPA provided figures of forest plots (in fact, to the commenter's point "as one would present in a meta-analysis") conveying associations between serum total cholesterol and PFOA or PFOS concentrations (e.g., see Figure 3-37 in USEPA, 2023f) and tables reporting associations in both serum lipids and other cardiovascular effects in Appendix D.5 (USEPA, 2023b; USEPA, 2023c). While the commenter critiques the EPA for not representing the "best available scientific approach to evaluating evidence," the commenter fails to recognize that this approach is based on and consistent with the agency's current gold standard for human health assessment methodology (USEPA, 2022a). The EPA also presented the integrated evidence in evidence profile tables (see Section 3.4.3.4.1, USEPA, 2023f; USEPA, 2023a). In addition, a meta-analysis for cardiovascular effects was presented in the *Economic Analysis of the Proposed National Primary Drinking Water Regulation for Per- and Polyfluoroalkyl Substances* (USEPA, 2023i), not in the public comment draft assessments.

American Chemistry Council (ACC) (Doc. #1841, SBC-052926)

PFOA and PFOS Exposure has not been Associated with Cardiovascular Disease in Multiple Epidemiology Studies

Despite a significant number of epidemiology studies investigating the potential association between exposure to PFOA and PFOS and an increased risk of cardiovascular disease (CVD), the evidence remains equivocal at best. As EPA notes, studies investigating CVD and atherosclerosis "reported mixed or primarily null [negative] results" and those evaluating blood pressure and hypertension "reported no effects or generally mixed associations." [FN55: USEPA. Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) in Drinking Water. Public Comment Draft. EPA Document No. 822P23005. Office of Water (2023), at 4-6. (USEPA PFOA MCLG Assessment 2023)], [FN56: USEPA. Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) in Drinking Water. Public Comment Draft. EPA Document No. 822P23007. Office of Water (2023), at 4-6. (USEPA PFOS MCLG Assessment 2023)] While there is evidence of an association between PFOS exposure and at least one measure of continuous blood pressure, there was not concordance among the endpoints within the study populations.

Although there is some evidence for an association with a modest increase in cholesterol and exposure to PFOA and PFOS, the increase does not correlate with increased CVD. Most recently a recent nested case-control study in Sweden study by Schillemanns et al. reported that exposure to five PFAS, including PFOA and PFOS, although associated with cholesterol levels, "did not associate with an increased risk of myocardial infarction, stroke or their composite endpoint." [FN57: Schillemans T et al. Per- and polyfluoroalkyl substances and risk of myocardial infarction and stroke: a nested case–control study in Sweden. Environ Health Persp 130(3):EHP9791.] While this study was published in early 2022, it was not identified by either EPA or the SAB. The lack of an association with CVD led the C8 Science Panel to raise the possibility that people with high cholesterol may retain PFOA, rather than PFOA being responsible for an increase in cholesterol. [FN58: Fletcher T et al. Probable Link Evaluation for heart disease (including high blood pressure, high cholesterol, coronary artery disease). C8 Science Pan http://www.c8sciencepanel.org/pdfs/Probable_Link_C8_Heart_Disease_29Oct2012.pdf]

Despite concluding that the epidemiology data do not support an association with PFOA and PFOS and CVD, EPA inexplicably develops an RfD for both substances based on evidence of an increase in total cholesterol.

EPA Response: Please see the EPA response to comment Doc. #1774, SBC-053211 and Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document regarding the EPA's consideration of studies reporting cardiovascular effects, including serum lipids, while synthesizing and integrating evidence for the cardiovascular health outcome. Regarding the EPA's selection of increased total cholesterol as a critical effect when data is limited for associations between PFOA or PFOS and CVD, please see section 4.2.2 of the EPA response in this *Response to Comments* document, as well as the EPA response to comment Doc. #1774, SBC-053429 in section 4.2.1.3 in this *Response to Comments* document. Regarding blood

pressure, please see the EPA response to comment Doc. #1713, SBC-053370 in this *Response to Comments* document. The agency did not conclude "that the epidemiology data do not support an association with PFOA and PFOS and CVD," but that the data were too limited to make conclusions regarding the association between PFOA or PFOS and CVD.

The commenter incorrectly claimed that the SAB and the EPA failed to identify a study published in 2022. First, Schillemans et al. (2022) postdated SAB review, which concluded in 2021, therefore it would have been impossible for the SAB to identify this study. Second, Schillemans et al. (2022) postdated the literature search conducted prior to public comment of the draft toxicity assessments, however the EPA has identified this study in the final updated literature review included in the final assessment (see section A-3 of the Appendix, USEPA, 2024d; USEPA, 2024c). The commenter misrepresented the findings from Schillemans et al. (2022) when suggesting that the study shows that although PFOA /PFOS were associated with cholesterol levels, there was no association with increased risk in other relevant cardiovascular endpoints (such as stroke, myocardial infarction, or other measures) in humans. The cholesterol levels and cardiovascular outcomes were not examined in the same subjects. In fact, the study shows that PFOS/PFOA were associated with increased cholesterol levels only in among the controls in the study (individuals without stroke or myocardial infarction). The risk of cardiovascular outcomes was analyzed comparing cases with stroke or myocardial infarctions and controls. Briefly, Schillemans et al. (2022) conducted population-based nested case-control study of Swedish adults (n = 1,528) within two cohorts: the Swedish Mammography Cohort-Clinical (SMC-C) and the Cohort of 60-year-old (60YO). In baseline cross-sectional analyses among 631 controls , baseline plasma PFOS was indeed associated with increased baseline TC (β per 1-SD-ln- ng/mL PFOS = 0.14, 95% CI: 0.06, 0.22), increased LDL-C (β = 0.13, 95% CI: 0.06, 0.20), increased HDL-C (β = 0.05, 95% CI: 0.01, 0.07), increased apolipoprotein A1 (β = 0.04, 95% CI: 0.02, 0.08), and decreased triglycerides (β = –0.11, 95% CI: –0.17, –0.05). In prospective analyses of the pooled cohorts, there were no significant associations between baseline PFOS and subsequent incidence of myocardial infarction, stroke, or CVD. Thus, this study evaluated associations between PFOS and elevated serum lipids among controls only; therefore, a conclusion about associations between PFOS and elevated CVD risk among individuals with elevated cholesterol levels cannot be made based on the study findings or data.

Mike Pettit (Doc. #1542, SBC-052837)

Cardiovascular effects: pg 267 reads "Epidemiology studies showed a positive association between PFOA or PFOS exposure and LDLC levels in children. In particular, the evidence suggested positive associations between serum PFOA and PFOS levels and LDLC levels in adolescents ages 12–18, while positive associations between serum levels and LDLC levels in younger children were observed only for PFOA. For instance, all five epidemiology studies evaluated in EPA's Proposed MCLGs for PFOA and PFOS in Drinking Water reported positive associations, although the association was only statistically significant in obese women. Available evidence regarding the impact of PFOA and PFOS exposure on pregnant women was too limited for EPA to determine an association."

A major issue is the lack of a clear mechanism by which PFoS exposure could lead to cardiovascular disease. While animal studies have suggested that PFOS exposure may lead to changes in lipid metabolism, inflammation, and oxidative stress, it is not yet clear how these effects may translate to humans or how they may contribute to cardiovascular disease. There is currently a lack of clear and consistent evidence linking PFOS exposure to cardiovascular effects in humans. While some studies have suggested an association between PFOS exposure and cardiovascular disease, others have not found a significant relationship. Additionally, animal studies have shown inconsistent results, with some indicating a link between PFOS exposure and cardiovascular effects, while others have not found any significant effects. A secondary thing of note, is that the only statistically significant finding was in obese women. There should be a red flag immediately brought up in this instance. This study does not take into account any of the other confounding factors having to deal with the potential reasons for heart disease in obese women. Clearly this claim should be taken into careful consideration.

EPA Response: The commenter stated that the mechanisms of action by which PFOS induces cardiovascular effects are unclear. The EPA agrees with this statement and directs readers to Section 3.4.3.3 of the PFOS toxicity assessment (USEPA, 2024c; USEPA, 2023a) which describes available mechanistic evidence supporting the effects of PFOS on the cardiovascular system. The mechanistic evidence is generally used to support the relevance of animal effects to humans and provide biological plausibility for evidence integration judgments but known mechanisms of action are not required for hazard identification or characterization (USEPA, 2022a).

Regarding the evidence for associations between PFOS and cardiovascular effects in humans, please see the EPA response to comment Doc. #1774, SBC-053211 and Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document. With respect to LDLC, the EPA disagrees that the only statistically significant finding was in obese women. Studies from the general population (Fan, 2020; Fitz-Simon, 2013; Lin, 2019 [PFOA only]) reported significant increases in LDL-C with elevated exposures to PFOA and PFOS. Additionally, studies published after our 2022 updated literature search have provided further evidence of significant associations between PFOS and LDL-C in adult populations (Batzella, 2022a; Batzella, 2022b; Cheng, 2022; Nilsson, 2022) (USEPA, 2024b, Sec. A-3). Additionally, a change or result that lacks statistical significance can be used to support a conclusion of an effect (Wasserstein and Lazar, 2016; USEPA, 2022a).

The EPA additionally disagrees with the commenter's assertion that the evidence from animal toxicological studies is inconsistent. As described in Section 3.4.3.4 of the PFOS toxicity assessment (USEPA, 2024a), alterations in serum lipids were reported in the majority of animal toxicological studies identified and reviewed by the EPA. These results are coherent with and support the evidence of altered serum lipids from human epidemiological studies.

Association of Metropolitan Water Agencies (AMWA) (Doc. #1738, SBC-053387)

CVD

In a study described in the 2016 Health Advisory (HA), no association with hypertension in 1,655 children aged 12–18 years from the NHANES was found [FN34: Wen-Wen Bao et al., "Gender-Specific Associations between Serum Isomers of Perfluoroalkyl Substances and Blood Pressure among Chinese: Isomers of C8 Health Project in China," Science of the Total Environment, 2017.]. An occupational study reported an inverse association for mortality from heart disease among all cohort members.

Since publication of EPA's 2016 PFOA health effect support document, EPA found 49 new epidemiological studies report on the association between PFOA and CVD, including outcomes such as hypertension, CAD, congestive heart failure, microvascular diseases, and mortality.

Of the ten studies that examined blood pressure as a continuous measure, six reported statistically significant positive associations [FN35: U.S. Environmental Protection Agency, "2023b," 3–151.]. EPA also points to two NHANES-based studies examining CVD that reported significant associations between PFOA and CVS [FN36: Anoop Shankar, Jie Xiao, and Alan Ducatman, "Perfluorooctanoic Acid and Cardiovascular Disease in US Adults," Archives of Internal Medicine, October 2012.]. However, another study using a larger NHANES dataset did not observe an association nor a positive trend between quartiles of exposure and CVD incidence [FN37: Mengmeng Huang et al., "Serum Polyfluoroalkyl Chemicals Are Associated with Risk of Cardiovascular Diseases in National US Population," Environment International, 2018.].

Some findings were mixed and inconsistent across studies. For those examining strokes, for example, one found a slight positive association [FN38: Huang et al.], while another observed a significant inverse association [FN39: Robert Hutcheson, Kim Innes, and Baqiyyah Conway, "Perfluoroalkyl Substances and Likelihood of Stroke in Persons with and without Diabetes," Diabetes and Vascular Disease Research, 2020.].

EPA Response: Please see the first EPA response to comment Doc. #1774, SBC-053211, and Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document and Doc. #1713, SBC-053370 in section 4.2.1.3 in this *Response to Comments* document regarding further discussion of the EPA's characterization of studies on blood pressure and CVDs. The EPA disagrees with the commenter that findings regarding association between exposure to PFOA and cardiovascular health outcomes were inconsistent across available studies and notes that the critical effect determined from the EPA's toxicity assessment as changes in total cholesterol in adults (USEPA, 2024d; USEPA, 2024c; USEPA, 2023f; USEPA, 2023a). Briefly, the cardiovascular studies included in these two assessments examined a large breadth of related cardiovascular endpoints without clear, pre-determined differences in potential toxicity, and, as a result, the evidence integration judgement was made for the larger cardiovascular health outcome category, which included serum lipids such as TC. As noted in the PFOA assessment (Section 3.4.3.4.1; USEPA, 2023a), there was generally consistent evidence of increased blood pressure in studies of general population adults. The number of studies examining associations between elevated exposure to PFOA and PFOS and incidence of CVD or CVD mortality were fewer and

typically of lower quality. Most studies on CVDs provided risk estimates for unique, non-overlapping definitions of disease which make evaluating consistency and coherence between studies difficult. Cardiovascular endpoints with higher quality studies (and usually a larger quantity of studies) drove conclusions for forming strength-of-evidence judgments. Judgments on endpoints with low confidence or limited evidence may obscure coherent effects for endpoints within the same health outcome category with higher quality evidence, and the ORD IRIS Handbook states that "the strongest evidence judgement will typically be used to reflect certainty in the broader health effect category," in the event of multiple evidence integration summary judgements for one health outcome category (USEPA, 2022a).

4.2.1.4 Consideration of Decreased Antibody Response as a Critical Effect

City of Lancaster, Pennsylvania (Doc. #1695, SBC-044993)

PFAS Study Conflicting Results: Although the USEPA proposes a very stringent contaminant level in its regulations, reducing the levels in water will not eliminate exposure to PFAS species PFOA/PFOS. Please reference the article - Does regulating per- and polyfluoroalkyl substances represent a meaningful opportunity for health risk Reduction? as published by AWWA. Furthermore, testing referenced in these studies (Dong, G.H. (2011)) shows that levels of exposure to PFOS that result in significant response were not significant from the control until dosages went to 5 mg/kg dosage per day (over 1.25 million times greater than reference dosages proposed). Other impacts did not occur significantly until 50 mg/kg dosages (12.5 million times reference dosages) for several factors monitored in the study.

A toxicological study performed by the group referenced in the (L. Zheng et al (2011)) performed another study on PFOS toxicological behavior based on monitoring short term dosage varied responses. The results of their study showed their data was discordant and not matching previous studies. The following was also stated:

"These discordant results are not apparently isolated to PFOS only. In studies of the effects of PFOA (physiochemically similar to PFOS) on immune functions in female C57BL/6N mice, Dewitt et al. (2008) found that SRBC-specific IgM synthesis was dose- dependently suppressed by PFOA, whereas SRBC-specific IgG titers were increased at lower (and similar to controls at higher) doses of PFOA. In contrast, Yang et al. (2002a) reported that PFOA exposure markedly suppressed the formation of both IgM and IgG antibodies against horse red blood cells."- L.Zhen et al. (2011)

This shows there are significant conflicting dosage response results seen with PFOS and PFOA and these studies warrant more research before relying on them to solely justify a dramatic shift in regulatory strategy and resulting investment for water systems. The proposed MCL bulletin states there is still not enough data for an MCL for the rest of the PFAS species. With this lack of data, the proposed limits for water being recommended are not warranted.

More recent studies from the Environmental Toxicology and Chemistry _Volume 40, Number 3-PP. 550-563 by Gloria B Post, have also shown lower refence dosages used by various states. The primary new concern with the lower dosages is the effect on the immune systems from babies. Though it touches on this and various other sources of exposure, it makes the key point that they still do not know much about the health effects of many of these species and they are making assumptions in the way of their overall health impacts and how they are studying them.

When reviewing this research, the key math being overlooked is that the volume of water needed to be consumed to reach the reference dosage of 2 ng/kg/L for an adult weighing 70 kg would with a source having 15 ng/L for an adult weighing 70 kg would be around 9.3 liters of water. That is over 2 gallons, and that individual would likely die from that volume of water consumption alone. Even with a baby of 22 lbs or 10 kg, the consumption of 1 liter of water is the maximum recommended. So, if the baby is drinking only water (which is not likely) with 15 ng/L of PFAS, the reference dosage would still not be reached.

The data shows that the new limit of 4 ng/L for the water is overkill and is unjustly going to put a financial burden on the citizenry when the primary exposures are coming from other sources USEPA is allowing to continue.

EPA Response: The commenter stated that the reduction of PFAS levels in drinking water does not present a meaningful opportunity for health risk reduction. The EPA disagrees with this statement: please see Section III of the preamble for this regulation and sections 3.1.3 and 3.2.3 of the EPA response in this *Response to Comments* document. The EPA disagrees that there is insufficient information to establish MCLs for PFOA, PFOS, PFHxS, PFNA, HFPO-DA and mixtures of PFHxS, PFNA, HPFO-DA, and PFBS regulated utilizing a hazard index approach. Additionally, as required under the Safe Drinking Water Act, the EPA has set the MCLs as close to the MCLGs as feasible using the best available treatment technology and taking cost into consideration. The EPA does not believe setting the PFOA and PFOS MCLs at 4.0 ng/L, a level that is as close to the PFOA and PFOS MCLGs as feasible, is "overkill" as claimed by the commenter; rather, setting them as close to the MCLGs of 0 as feasible is the EPA's obligation under the SDWA statutory construction. See discussion in section V of the preamble of the PFAS NPDWR and section 5 of the EPA response in this *Response to Comments* document.

The commenter cited several animal toxicological studies as evidence that the immunotoxic effects of PFOA and PFOS are inconsistent and only occur at levels that are not relevant to human exposure. The EPA disagrees with these statements. The commenter appears to ignore the evidence of immunotoxicity from studies in humans (e.g., reduced antibody response to vaccination). As described in Sections 3.4.2.4 and 4.1.1.2 of the PFOA and PFOS toxicity assessments (USEPA, 2023f; USEPA, 2023a), results reported in animal toxicological studies are consistent with the observed immunosuppression in epidemiological studies. The epidemiological evidence consistently demonstrated reduced antibody response at median levels as low as 1.1 ng/mL PFOA. The commenter also ignores that the EPA quantified the immune health outcome RfD based on decreased antibody concentrations in children. Most importantly,

the commenter incorrectly stated that EPA relied on the cited immunotoxicity studies in animals "to solely justify a dramatic shift in regulatory strategy." The MCLGs are based on the determination that PFOA and PFOS are *Likely to be Carcinogenic to Humans,* not on an RfD derived from immunotoxicity data.

Further, the consistency of the animal toxicological database individually is presented in the evidence profile table in Section 3.4.2.4 (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). The commenter also appears to misunderstand extrapolation of data from dosed animal toxicological studies to human exposure. While the EPA agrees that there are uncertainties associated with the extrapolation of data from animal models to humans (see discussion in the EPA Response below), including several that the commenter highlighted above, the EPA disagrees that this precludes the agency from quantitatively relying on studies in animal models for the derivation of toxicity values. This practice has been used to support EPA products for decades and is repeatedly endorsed by the EPA guidance and methods (USEPA, 2002; USEPA, 2005; USEPA, 2014a; USEPA, 2022a). The EPA agrees that extrapolation from animal models to humans is complex, but animal toxicological studies, regardless of study design characteristics such as dose levels, are critical for determining potential human health hazards and the exposure levels and internal doses (e.g., serum concentrations) that may be expected to cause adverse health effects in humans. With an understanding of how the chemical exposure behaves differently in animals and humans, the EPA can estimate the equivalent level of exposure that would pose a risk to human health and compare those values across any effects that could pose a hazard. In this way, the EPA can determine the minimum exposure level (e.g., RfD) that could result in a risk to human health. The pharmacokinetic approach the EPA used to estimate human equivalence doses from animal toxicological studies is available in Section 4.1.3 of the PFOA and PFOS toxicity assessments (USEPA, 2023f; USEPA, 2023a). The EPA did not ignore this "key math" and in actuality implemented a more sophisticated approach than recommended by the commenter. There are fundamental toxicokinetic concepts which are ignored in the commenter's description of the volume of water required to reach the reference dose, such as the absorption, distribution, metabolism, and elimination of PFOA and PFOS in humans. PFOA and PFOS are both highly persistent chemicals with long reported half-lives generally ranging from 2 to 5 years in adults (USEPA, 2023f, USEPA, 2023a, Sec. B.4.5). Considering the length of the half-life for each substance (i.e., slow elimination), and that PFOA and PFOS both accumulate and are distributed in various tissues (USEPA, 2023f, USEPA, 2023a, Sec. B.2.2.1), calculating the amount of water necessary to reach a reference dose would not be as simple as the commenter suggests.

3M Company (Doc. #1774, SBC-053219)

v. EPA's assessment of immunotoxicology is inconsistent with agency guidance.

In assessing immune efforts, EPA did not appropriately employ methods described in the IRIS Handbook for evaluation of study quality and risk of bias in evaluating vaccine repose. EPA did not evaluate evidence consistently across studies, nor did it synthesize evidence according to

guidance. This omission again led to the selection of candidate studies for point of departure (POD) development with critical limitations. Selection of reliable studies with limited bias is critically important for limiting the uncertainty in the derived POD and subsequent toxicity values. If EPA had appropriately refined the study evaluation to the vaccine endpoint, thus accounting for aspects SAB recommended, a high level of uncertainty would have been found in the body of evidence. EPA failed to follow IRIS guidance to refine the study evaluation tool to the topic, including modifications to evaluation criteria to include factors specific to the exposure and outcome of interest, as well as potential confounders that specifically affect these associations. Such considerations would allow for the evaluation of specific factors critical to the overall study reliability conclusions. As a result of these process errors, the evidence presented does not support antibody response to vaccine as a critical endpoint and leads to a high level of uncertainty in the calculated toxicity values derived for this endpoint.

EPA (USEPA 2023a,b) considered multiple outcomes under the category of immune function, including vaccine response, infectious disease, immune hypersensitivity (allergy, asthma), and autoimmune disease. EPA determined that there was moderate evidence for an association between PFOA/PFOS exposure and immunosuppressive effects in human studies. This conclusion was based on its findings in PFOA studies of "largely consistent decreases in antibody response following vaccinations (against two different infectious agents: tetanus and diphtheria) in multiple medium confidence studies in children" (USEPA 2023a, p. 3-133), and a "largely consistent decrease in antibody response following vaccinations (against three different infectious agents) in multiple medium confidence studies in children" for PFOS (USEPA 2023b, p. 3-122). However, uncertainties in the conclusions for both PFOA and PFOS reflect:

· Inconsistent findings of decreased vaccine response in adult populations

· Inconsistent and/or imprecise findings of increased infectious disease

· Mixed findings of hypersensitivity, including allergy, asthma, and eczema

· Mixed findings for autoimmune disease

Additional details regarding the strength of evidence for outcomes related to immune function are described in the EPA Evidence Stream and Summary Judgments (USEPA 2023a, Table 3-7; USEPA 2023b, Table 3-10).

EPA Response: The commenter incorrectly stated the EPA did not appropriately employ study quality evaluation methods for evaluating vaccine response, consistently evaluate evidence across studies, or synthesize evidence according to guidance and SAB recommendations. Please see the EPA Responses to sections 4.1.1, 4.1.2 and 4.1.3 in this *Response to Comments* document.

The commenter suggested this led to the selection of studies inappropriate for POD derivation and incorrect conclusions about the body of evidence. The commenter raised uncertainties in the conclusions such as inconsistent findings of vaccine response in adults, inconsistent or imprecise

findings for infectious disease, mixed findings for immune hypersensitivity, and mixed findings for autoimmune disease. The EPA disagrees with these claims.

The EPA disagrees that modifications made to the PFOA and PFOS systematic review protocols were insufficient. As highlighted in responses to the same commenter under sections 4.2.1.2 and 4.2.1.3, the EPA modified the study quality evaluation criteria based on considerations described in the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a), as well as the *Systematic Review Protocol for the PFAS IRIS Assessments* (USEPA, 2021a). Exposure-specific modifications were appropriately made to the criteria in consultation with a topic-specific technical expert. Due to the breadth and heterogeneity of outcomes evaluated in the evidence base, the EPA determined outcome-specific evaluation criteria were not necessary. It is unclear which SAB recommendation the commenter is referring to in suggesting the creation of vaccine response-specific evaluation criteria for Outcome Ascertainment and the EPA could find no such recommendation (USEPA, 2022b). The EPA considered additional chemical-, exposure-, and outcome-specific factors when reviewing studies for use in quantitative analyses consistent with ORD Handbook (USEPA, 2022a).

The EPA disagrees with the commenter's characterization of inconsistencies in studies of vaccine response in adults. There were a limited number of studies, especially High confidence studies, which analyzed vaccine response in adults. Specifically, there were only 5 studies that explored vaccine response in adults; three out of the five total studies were rated as Low confidence and each study analyzed different antibody titers (e.g., hepatitis A, hepatitis B, and influenza), which makes comparisons between studies difficult (Section 3.4.2.1, USEPA, 2024d; USEPA, 2024c; USEPA, 2023f; USEPA, 2023a). The difficulty in comparing these limited studies does not negate the findings from studies of vaccine response in children, especially considering the increased number of total studies (12), confidence in those studies (9 medium and 1 high confidence) and consistency of results observed in studies of children. Given these factors, the EPA maintains its position that vaccine response in children is an appropriate critical effect considered for quantitative analyses, a position that was supported by the EPA's SAB PFAS Review Panel (USEPA, 2022b).

Positive associations or increased risk of adverse health outcomes should not be ignored, even if some inconsistency is present in the evidence base. Complete consistency within an outcome category is not an expectation of a body of observational studies in humans, and some inconsistency is expected due to differences in study populations. For example, studies analyzing infectious disease examined numerous types of conditions, and, in some cases, analyzed "total infections," which may refer to various groupings of different infections. There were numerous infectious diseases examined in single studies, such as cytomegalovirus, Epstein Barr virus, hepatitis C and E, herpes simplex 1 and 2, HIV, Toxoplasma gondii and Toxocara species (Bulka, 2021). Even within a more granular category of infectious disease (e.g., respiratory tract infections) the studies still varied in their reporting of risk estimates, including for outcomes such as throat infection (Impinen, 2019), recurrent respiratory infection (Huang, 2020), lower respiratory tract infection (Kvalem, 2020; Impinen, 2018; Dalsager, 2021), upper respiratory

tract infection (Dalsager, 2021), syncytial virus and pseudocroup (Ait Bamai, 2020; Kvalem, 2020), or just "infections" generally (Abraham, 2020; Wang, 2022). The heterogeneity of how each study examined the presentation of infectious disease may lead to perceived inconsistencies in the evidence base, however, not all conditions described above can be directly compared. Other studies examined symptoms only (e.g., fever, diarrhea, coughing), which are difficult to attribute to a specific condition (Timmerman, 2020). The type of allergies examined in studies of hypersensitivity also included a wide variety of allergens and allergy tests conducted at various ages allergic rhinitis or rhinoconjunctivitis (Goudarzi, 2016; Ait Bamai, 2020; Impinen, 2018; Kvalem, 2020; Timmermann, 2017), skin prick test (Kvalem, 2020 and Impinen, 2018 at age 10 years; Timmermann, 2017 at age 13 years), and food or inhaled allergies(Kvalem, 2020, and Impinen, 2018, at age 10 years; Timmermann, 2017, at age 13 years}). Similar to infectious disease, if the number studies examining the same allergen or allergy test are limited, then direct comparability between studies is also limited. The availability of such studies is unrelated to the presence or absence of an adverse effect. Similarly, the evidence base for autoimmune disease examined a variety of different conditions (e.g., multiple sclerosis in Ammitzbøll, 2019; ulcerative colitis in Xu, 2020; and rheumatoid arthritis in Steenland, 2013), making comparisons across studies difficult. These considerations were outlined in the Evidence Integration for Immune studies (USEPA, 2023f; USEPA, 2023a, Sec. 3.4.2.4), including the Evidence Profile Table (Table 3-7).

3M Company (Doc. #1774, SBC-053430)

EPA's failure to conduct a transparent and consistent evaluation of the evidence base for immune outcomes led to selection of candidate studies with critical limitations.

Under the category of immune effects, EPA (2023a,b) considered multiple outcomes, including vaccine response, infectious disease, immune hypersensitivity (allergy, asthma), and autoimmune disease. EPA (2023a,b) determined that there was moderate evidence for an association between PFOA/PFOS exposure and immunosuppressive effects in human studies. This was based on its findings in PFOA studies of "largely consistent decreases in antibody response following vaccinations (against two different infectious agents: tetanus and diphtheria) in multiple medium confidence studies in children" (2023a, p. 3-133), and in PFOS studies a "largely consistent decrease in antibody response following vaccinations (against three different infectious agents) in multiple medium confidence studies in children" (EPA 2023b, p. 3-122). However, there were significant uncertainties in EPA's conclusions for both PFOA and PFOS due to:

· Inconsistent findings of decreased vaccine response in adult populations

· Inconsistent and/or imprecise findings of increased infectious disease

· Mixed findings of hypersensitivity, including allergy, asthma, and eczema

· Mixed findings for autoimmune disease

Additional details regarding EPA's assessment of the strength of evidence for outcomes related to immune function are described in the EPA Evidence Stream and Summary Judgments (EPA 2023a, Table 3-7; EPA 2023b, Table 3-10).

Despite this, EPA did not evaluate evidence consistently across studies, nor did it synthesize evidence according to its guidance. This led EPA to select candidate studies for POD development with critical limitations.

If EPA had appropriately refined the study evaluation for the vaccine endpoint, thus accounting for aspects SAB recommended, the agency likely would have found a high level of uncertainty in the body of evidence such that the use of vaccine response as a critical endpoint is not supported.

EPA did not appropriately explain whether or how it accounted for the lack of consistency or plausibility demonstrated within the evidence base for vaccine response and incidence of infectious disease.

EPA's summary of infectious disease incidence associated with PFOA or PFOS exposure indicated that results were not consistent across studies, finding that "Increased incidence of some infectious diseases in relation to PFOA exposure was observed, although results were not consistent across studies" and stating there is "limited evidence of an association between PFOS exposure and infectious diseases." (EPA 2023a, p. 3-106; EPA 2023b, p. 3-123).

Similarly, epidemiologic studies on hypersensitivity and autoimmune disease reported mixed associations with PFOA exposures (EPA 2023a, p. 3-134). Epidemiologic studies reported some evidence of sensitization and allergic responses with PFOS, but "notable limitations and uncertainties in the evidence base remain" (EPA 2023, p. 3-123). Specifically, EPA states "While there is some evidence that [PFOA and PFOS] exposure might also have the potential to affect sensitization and allergic responses in humans given relevant exposure circumstances, the human evidence underlying this possibility is uncertain and with limited support from animal or mechanistic studies." (EPA 2023a, Table 3-7; EPA 2023b, Table 3-10). Some evidence of an association between PFOS and asthma was observed, but EPA noted "considerable uncertainty due to inconsistency across studies and subgroups." (EPA 2023b, p. 3-123). EPA did not provide justifications or clearly state the strength of evidence for each of the immune endpoints, thereby limiting transparency in its selection of the critical effect for POD derivation. [FN2: Decreases in vaccine response can be a risk factor for infectious disease, but they are not necessarily adverse effects themselves. To be adverse, immunosuppressive effects must result in an increase in infectious disease incidence.]

EPA did not provide a transparent description of its approach to accounting for uncertainties and unsupportive toxicological studies in its evidence integration approach and methods. In addition, EPA failed to address the implications of the lack of clear mechanistic support and biological relevance and plausibility on its choice of vaccine response as a critical endpoint. The lack of such explanation is critical given that the underlying evidence does not demonstrate a clear or consistent relationship within the dataset, nor does it demonstrate a clear or consistent relationship with adverse outcomes (incidence of infectious disease). Without additional

explanation, the public cannot provide input regarding the agency's interpretation of the available evidence.

In contrast with best practices in systematic review, and in contrast with its own guidance, EPA did not evaluate study quality consistently for the immune evidence.

The SAB urged EPA to implement a consistent process with consistent terminology for analyzing and synthesizing evidence. In response, EPA said it expanded the systematic review steps to be consistent with the IRIS Handbook to ensure this was accomplished (EPA 2023c, p. 16). However, EPA did not follow guidance presented in the IRIS Handbook that asks the reviewer to re-read the studies after the initial evaluation of evidence for a particular health outcome and consider, "Have the evaluation judgments been consistently applied across the set of studies?" (EPA 2022). Rather, EPA's Study Quality Evaluation shows that the EPA inconsistently applied the risk of bias considerations. Within specific domains, some studies were downgraded for biases when other studies with similar characteristics were not (examples provided below).

As an example of EPA's inconsistent approach to the risk of bias in studies, the agency failed to equally evaluate temporality across all studies. In the IRIS assessment criteria for evaluating exposure measurement, a study should be given a rating of "critically deficient" for this domain if "There is evidence that reverse causality is very likely to account for the observed association" (EPA 2023d,e). Critically deficient studies should not be considered for a candidate study.

Based on this guidance, cross-sectional studies are of uncertain reliability because they measure exposure and outcome at the same time and cannot establish temporality between exposure and outcome. Reverse causation is a concern with these types of studies. EPA notes this concern and limitation for certain cross-sectional studies, such as Pilkerton et al. (2018), which examined serum PFOA/PFOS concentrations and vaccine response among NHANES participants. EPA stated that the analysis of adults in Pilkerton et al. (2018) "suffered from potential exposure misclassification due to concurrent exposure and outcome measurements and was also rated low confidence" (EPA 2023a, p. 3-104).

However, one of the candidate studies chosen was a cross-sectional study of Greenlandic children (Timmermann et al. 2022), which the agency gave an overall "medium" quality rating. This study is a cross-sectional study like Pilkerton et al. (2018). Therefore, it should have been considered critically deficient. The inconsistent application of confidence ratings based on the temporal limitations of cross-sectional analyses show that EPA did not consistently apply evidence judgements, as proscribed in the IRIS (EPA 2022) Handbook.

Biases in the assessment of exposure to PFAS were not consistently evaluated. EPA rated some studies as "Good" for this domain specifically because maternal samples were taken in early pregnancy and therefore had a low risk of bias. For example, the HAWC assessment details for Bjerregaard-Olesen (2019) state, "Exposure measurement error is expected to be minimal given the long half-life and high-quality exposure data that were collected (and analyzed); as such, the first trimester samples are anticipated to be appropriate to capture critical windows of interest." (EPA 2023f). Another study of PFAS and fetal growth outcomes analyzed PFAS measures taken

during each trimester and in cord blood during delivery, and was rated "Good" for Exposure Assessment because multiple samples across different trimesters was a strength. Further, EPA noted that primary analyses were performed with the earliest samples (trimesters 1-2), because these measures were reflective of critical in utero windows and minimal measurement error was anticipated (Chen 2021). Had the timing of the exposure measures been consistently evaluated, Grandjean et al. (2017) would not have been rated as Good", but rather "Deficient" in this domain, because maternal serum PFAS was measured in the third trimester and therefore has an increased risk of bias.

It is critical that EPA follow its own guidance and evaluate all studies consistently to determine the risk of bias and uncertainty within the body of evidence and choose appropriate candidate studies. EPA's failure to consistently apply critical appraisal ratings resulted in EPA choosing inappropriate or lesser confidence studies as candidate studies and therefore substantial uncertainties in toxicity value derivation.

EPA did not synthesize evidence in accordance with SAB recommendations or agency guidance because the agency omitted several studies from the body of evidence synthesis of vaccine response, and thus the endpoint was selected for POD derivation without consideration of the full body of evidence.

EPA did not follow the SAB's recommendation to consider the evidence from all medium confidence studies and provide reasoning for excluding any of those studies. The SAB recommended, "Consideration of all human studies is especially important because conclusions about the human health effects, which are generally observational rather than experimental, are based on the overall weight of evidence and should include all relevant data. [Emphasis added]" (EPA 2023c, p. 20). This recommendation was intended to help the agency make a sound scientific judgement on potential candidate studies after evidence integration. In response, EPA said it "revised the noncancer health effects synthesis and integration sections to provide a more detailed and consistent framework for study quality evaluation, evidence synthesis, and evidence integration for each health outcome following the IRIS Handbook." (EPAc, p. 20).

When synthesizing the evidence for vaccine response with PFOA exposure, EPA found, "largely consistent decreases in antibody response following vaccinations (against two different infectious agents: tetanus and diphtheria) in multiple medium confidence studies in children" (EPA 2023a, p. 3-133). Of the 6 medium confidence studies conducted in children, vaccines against 5 different infectious agents were investigated. It is unclear which studies EPA included in the evidence integration, but from the above statement, it was not all eligible studies.

Similarly for PFOS, the evidence integration concluded that there is a "largely consistent decrease in antibody response following vaccinations (against three different infectious agents) in multiple medium confidence studies in children." (EPA 2023b, p. 3-122). Of the 6 medium-confidence studies conducted in children (Grandjean et al. 2017a,b; Granum et al. 2013; Timmermann et al. 2020, 2022; Mogensen et al. 2015), vaccines against 5 different infectious agents were investigated. As with the PFOA evidence integration, it is unclear which studies

were included in the PFOS evidence integration, but again it appears it was not all eligible studies.

Thus, EPA did not synthesize all of the evidence, contrary to the SAB's recommendation and the SDWA's requirement that the agency consider the best available scientific information.

EPA also did not provide justification for its exclusion of some medium confidence studies on vaccine response when selecting a candidate study for POD derivation. This lack of explanation is contrary to the SAB's recommendation that the agency more clearly present the rationale and criteria for selection of endpoints and specific studies for POD development (EPA 2023c, p. 37). EPA responded that "multiple medium-confidence studies were considered for POD derivation: Budtz-Jørgensen and Grandjean (2018), Timmerman et al. (2021), Granum et al. (2013) and Looker et al. (2014)." (EPA 2023c, p. 37). However, the agency gave no explanation for why the remaining medium confidence studies in children that showed inconsistent evidence (e.g., Pilkerton et al. 2018; Timmermann et al. 2020; Mogensen et al. 2015) were not also considered. EPA cited Mogensen et al. (2015) in the list of Faroe Islands cohorts that had significant associations but ignored that significance was lost when other PFAS exposures were included in the models.

EPA's failure to follow SAB and IRIS Handbook guidance regarding consistent evidence integration resulted in inconsistent findings and biased choice of candidate studies. EPA did not provide sufficient discussion of the rationale for inclusion and exclusion of evidence from the final evidence integration and judgement for vaccine response as a critical endpoint.

EPA Response: The commenter stated there were significant uncertainties with the EPA's *Moderate* evidence stream judgement for immune effects in humans. The uncertainties cited by the commenter include inconsistent findings for vaccine response in adults, inconsistent or imprecise findings for infectious disease, mixed findings for hypersensitivity, and mixed findings for autoimmune disease. The commenter also claimed that the EPA did not consistently evaluate or synthesize evidence according to its guidance. The commenter stated that these factors combined suggest the EPA should not consider vaccine response as a critical endpoint. These comments are redundant with those provided by the commenter in another section; the EPA disagrees and provides an explanation as to why in the EPA response to comment Doc. #1774, SBC-053219 in section 4.2.1.4 in this *Response to Comments* document.

The commenter also asserted the EPA did not clearly state the strength of evidence for each immune endpoint, limiting the transparency of critical effect selection for POD derivation. however,, the EPA clearly states in the MCLG Appendix (A.1.10) that "strength-of-evidence judgments were made for each health outcome," which does not require a strength-of-evidence judgment for each individual immune endpoint (USEPA, 2023c; USEPA, 2023d). IRIS guidance states that multiple judgements for a health outcome category may be made, but this is a pre-determined decision, and considering the breadth of the endpoints examined in all included immune studies the EPA chose to make one evidence integration summary judgement for all immune health outcomes (USEPA, 2022a). Regardless of the decision to make separate or

combined evidence stream or summary integration judgements, assessment methodology from the ORD IRIS Handbook states that "the strongest evidence judgement will typically be used to reflect certainty in the broader health effect category," in the event of multiple evidence integration summary judgements for one health outcome category (USEPA, 2022a). In other words, this decision has no bearing on the overall conclusions for the immune or other health outcomes.

Further, the Evidence Profile Tables (EPTs) provided for each priority health outcome are completed in order of the strength of evidence and importance to the overall Health Outcome Category evidence summary judgment (i.e., Immunosuppression is discussed first, as the driving factor is antibody response). Coherence between immunosuppression, hypersensitivity, and autoimmune disease is not necessarily expected. There may be biological or mechanistic reasons for differences between immune endpoints and the commenter does not provide any evidence or citations to EPA guidance or best practices that coherence across every endpoint in necessary to conclude that the evidence indicates an association. Coherence between endpoints may also be restricted due to data limitations. For both PFOA and PFOS, the evidence base for autoimmune disease is comprised primarily of *low* confidence studies, which limits the EPA's ability to assess this endpoint.

Regarding consistencies between studies reporting on the same endpoint, the EPA disagrees with the claim that data from epidemiological studies were unable to demonstrate a clear relationship between exposure and the immune suppression. Differences in magnitude of effect or differences between categorical exposure groups may also depend on dose response curves that require further analysis, but do not negate the observed effect. Thus, complete consistency between studies using observational data is not realistic.

Second, the EPA provides descriptions on how data from all evidence streams, including mechanistic and toxicological studies, were considered in the evidence integration summary judgement located in Table A-41 (USEPA, 2023b; USEPA, 2023c). It is unclear how the commenter determined that toxicological studies were unsupportive of effects in humans and the commenter does not provide supporting evidence regarding this criticism. In Section 4.1.1.2 of the PFOA and PFOS assessments, the EPA stated: "Results reported in animal toxicological studies are consistent with the observed immunosuppression in epidemiological studies" (USEPA, 2024d; USEPA, 2024c; USEPA, 2023f; USEPA, 2023a). For both chemicals, there was coherent evidence of immunosuppression observed by several animal toxicological studies reporting results of functional assessments of immune responses (e.g., Natural Killer cell activity, immunoglobulin response, plaque-forming cell response).

Third, the EPA disagrees with the commenter's stated implication of the lack of mechanistic support. An explanation is provided in Appendix A Table A-41 (USEPA, 2023b; USEPA, 2023c) which states the determination of "evidence indicates (likely)" may be based on "moderate human evidence when strong mechanistic evidence is lacking." Further, according to the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022), mechanistic evidence "can provide support for the relevance of animal effects to humans and biological plausibility for

evidence integration judgments" or provide "information on potentially susceptible populations and lifestages or data that could inform the shape of the dose-response curve (i.e., if the available human data have substantial quantitative uncertainties)." For both PFOA and PFOS, there is coherent evidence of immunosuppression in both animal toxicological and human epidemiological studies, the epidemiological studies investigate a susceptible population (i.e., children), and there are not substantial quantitative uncertainties requiring strong mechanistic support. Therefore, limited insight into the know mechanisms of action does not impact the EPA's conclusions regarding the immunological effects of PFOA and PFOS.

Finally, regarding a consistent relationship with incidence of disease, the SAB panel noted "clinical manifestation of a disease is not a prerequisite for a chemical to be classified as an immunotoxic agent" (USEPA, 2023a, p. 4–5). Antibody response is a translatable outcome across species, and the SAB panel specifically stated "[d]ecreased antibody responses to vaccines is relevant to clinical health outcomes and likely to be predictive of risk of disease" (USEPA, 2022,a). The EPA has added additional justification regarding the adversity of the endpoint selected for POD derivation in Section 4.1.1.2 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c). Both the SAB PFAS Review Panel (USEPA, 2022) and the EPA agree that a reduction in the level of antibodies produced in response to a vaccine represents a failure of the immune system to respond to a challenge and, thus, should be considered an adverse immunological health outcome. The World Health Organization (WHO) has also concluded that "childhood vaccine failures represent a significant public health concern" (WHO, 2012).

The commenter additionally suggested the EPA did not follow its own guidance on study quality evaluation based on perceived discrepancies in applying risk of bias considerations within domains. The commenter provided an example of perceived inconsistent application of reverse causality in the exposure assessment domain by noting cross-sectional studies were not rated critically deficient when exposure and outcome were measured concurrently. The commenter provided another example of perceived inconsistent application of risk of bias considerations for exposure assessment, citing timing of exposure measurement in pregnancy for developmental and immune outcomes.

The EPA disagrees that it did not follow its own guidance on study quality evaluation. The study evaluation protocols used for the assessments of PFOA and PFOS were consistent with protocols provided in both the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a) and the *Systematic Review Protocol for the PFAS IRIS Assessments* (USEPA, 2021a). Please also see the EPA response to section 4.1.1. Any perceived discrepancies in the EPA's application of risk of bias considerations is based on incomplete information and clarified in the following responses.

As discussed previously, the EPA disagrees that reverse causality is a concern in all cross-sectional studies. Reverse causality is dependent on biological considerations for the outcome of interest, as noted in the footnote of Table A-19 (USEPA, 2023b, USEPA, 2023c). In cross-sectional studies, outcomes that may impact the absorption, distribution, metabolism, or elimination of PFOA or PFOS in the body (i.e., the measured exposure) would elicit concern for

reverse causality. Examples of outcomes that impact the measured exposure levels of PFOA or PFOS have been described in the literature (Radke et al., 2019). Reverse causality is not directly relevant to immunotoxic effects, such as decreased antibody response observed in Pilkerton et al. (2018) and the commenter does not provide any evidence that reverse causality is a concern for immunotoxic effects. Furthermore, the evaluation for Pilkerton et al. (2018) was split by population, namely children and adults. The analysis of children was considered *medium* confidence, with justifications consistent with those described in the evaluation of Timmerman et al. (2021). The analysis of adults in Pilkerton et al. (2018) was considered *low* confidence due lack of information related to timing of vaccination or previous infection. Concurrent PFAS exposure measurements are representative of recent past exposure, however, for adults this may be less representative due to the large amount of time elapsed between vaccination (i.e., typically in childhood) and exposure measurement (i.e., ≥ 19 years of age). Additionally, there was no information on vaccination status, vaccination timing, prior infections, or variation in vaccination schedules, all of which may affect seropositivity in adults. Due to the considerable differences in potential for bias between adult and children in Pilkerton et al. (2018), separate ratings were justified and were not inconsistent with Timmerman et al. (2021).

The EPA also disagrees that considerations for exposure timing in pregnancy were inconsistently applied. The commenter appears to suggest that simply the presence of samples in a later trimester of pregnancy would automatically result in a "Deficient" rating for Exposure Assessment, which is incorrect. The PFAS-specific exposure assessment criteria (Table A-19) includes considerations for critical exposure windows based on the outcome: "exposure was assessed in a relevant time-window (i.e., temporality is established, and sufficient latency occurred prior to disease onset) for development of the outcome based on current biological understanding" (USEPA, 2023b; USEPA, 2023c). Study quality evaluations of studies investigating fetal growth restriction included judgements based on whether exposure measurement was representative of *"critical in utero windows,"* which is consistent with the study quality evaluation considerations outlined in the developmental synthesis (USEPA, 2023f, p. 3-193–194). Based on the estimated long half-lives of PFAS in humans (USEPA, 2023f, Sec. 3.3.1.4.5), exposure measurements taken during any trimester of pregnancy would be considered adequately representative. Bjerregaard-Olesen (2019) and Chen et al. (2021) had well described and documented exposure assessment methods, resulting in *Good* ratings for Exposure Assessment as a result. Likewise, Grandjean et al. (2017), had well described and documented exposure assessment methods and was also rated Good.

The commenter stated the EPA did not follow SAB's recommendation to consider all *medium* confidence studies in evidence integration. To demonstrate this, the commenter provided the example of the EPA's PFOA synthesis of tetanus and diphtheria vaccine response in children, suggesting the synthesis demonstrates that the EPA did not consider studies on vaccine response to other pathogens. A similar example for PFOS was provided. The EPA disagrees with these comments.

The studies identified by the commenter altogether address vaccine response to five different pathogens for PFOA (i.e., tetanus, diphtheria, rubella, influenza, and measles) and six for PFOS (i.e., tetanus, diphtheria, rubella, measles, and hepatitis A and B). However, for PFOA only three of those pathogens (i.e., tetanus, diphtheria, and rubella) were evaluated in more than one *medium* confidence study on children. Similarly, for PFOS, evidence for vaccine response to pathogens other than tetanus and diphtheria was only reported in two studies or less. In contrast to the commenter's claims, all available studies were synthesized in Section 3.4.2.1. Evidence integration for the immune health outcome also considered all studies addressing vaccine response in children, however, conclusions regarding the weight of evidence for this endpoint were based primarily on vaccine responses with multiple *medium* or *high* confidence studies, as these provided a stronger evidence base than responses with only one or two studies. Conclusions for vaccine responses to other pathogens besides diphtheria and tetanus (e.g., measles and Hib) were limited by the number of studies reporting an association and, in some cases, the confidence in the limited available studies.

The commenter also stated that the EPA did not provide adequate justification for the selection and exclusion of candidate studies reporting antibody responses for POD derivation. The EPA disagrees with this claim. The EPA outlined considerations for study selection (USEPA 2023f; USEPA, 2023a, Section A.1.11) which draws on guidance provided in the IRIS Handbook (USEPA, 2022a). The IRIS Handbook (USEPA, 2022a) outlines additional factors that can be considered during study selection beyond study confidence, including factors such as exposure timing and study design. The commenter provides examples of studies not considered by the EPA; these studies were considered but not selected for POD derivation for various reasons, including data availability for modeling (Pilkerton et al., 2018), lack of supporting evidence from additional studies on the specific response observed for that vaccine (e.g., measles for Timmerman et al., 2020), and overlapping populations with other studies (e.g., data from Mogensen et al., 2015 overlap with data from Grandjean et al., 2017). To increase transparency of these decisions, the EPA has provided additional discussion on candidate study selection to Section 4.1 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c). The IRIS Handbook also states that "consideration of the consistency in patterns of results does not require that all findings are statistically significant" (USEPA 2022a, p. 6–19).

<u>3M Company (Doc. #1774, SBC-053229)</u>

2. EPA did not appropriately employ methods described in the IRIS guidance for evaluation of study quality and risk of bias in evaluating vaccine response.

EPA's failure to follow its IRIS Handbook for evaluation of study quality and risk of bias led it to reach conclusions opposite those that would have been reached by an independent assessment of the evidence that did follow EPA's IRIS Guidance. According to IRIS guidance, additional chemical, outcome, or exposure-specific considerations for evaluating studies should be developed in order to identify issues that would be expected to result in critical biases and reduce the confidence rating of a study (USEPA ORD 2022, p. 4-2). Based on this guidance, the criteria

for assessing bias in several of the evaluation domains (exposure assessment, outcome ascertainment, confounding, and sensitivity) should have accounted for factors specific to the exposure and outcome of interest, as well as potential confounders that specifically affect these associations. Such considerations would allow for the evaluation of specific factors critical to the overall study reliability conclusions.

An independent assessment was performed by ToxStrategies for studies examining vaccine response and PFOA exposure using the same IRIS framework for systematic review and critical appraisal of studies used by the EPA in the draft toxicity assessment for PFOA (USEPA 2023a, p. 1-10). See Appendix A. The independent assessment followed the IRIS guidance to modify several of the evaluation domains specific to the topic in order to identify critical issues regarding study quality and risk of bias, including consideration of factors that are specific to either the exposure, outcome ascertainment, confounding factors that affect the association of interest, and sensitivity issues including external validity and study construct. In contrast, the only apparent modification EPA made to its tool was to the exposure assessment domain criteria. This and missed critical issues that could render studies unreliable for dose-response assessment.

After identification and critical appraisal of studies examining vaccine response and PFOA exposure in the independent assessment, all studies received an overall rating of "deficient" or "critically deficient." Each study had deficiencies in participant selection, timing of exposure and outcome measures, or confounding, which resulted in a body of evidence that was of low quality with a high risk of bias. Based on these findings, vaccine response was not considered a critical endpoint for PFOA exposure, and no studies qualified for POD development.

Significant additional flaws and limitations in EPA's assessment of immunotoxicology, including EPA's failure to consider the conclusions of other agencies regarding immune effects as a critical endpoint (and the Grandjean et al. (2012) study in particular), are described in further detail in Appendix A.

EPA Response: The commenter stated the EPA did not follow the EPA's IRIS guidance during study quality evaluation. The commenter stated chemical-, outcome-, and exposure-specific considerations should have been included in adapted study evaluation criteria. These comments are redundant with those provided by the same commenter in an appendix to their comment letter; the EPA disagrees and provided a rebuttal in the EPA response to comment Doc. #1774, SBC-053219, Doc. #1774, SBC-053430, and Doc. #1774, SBC-053229 in section 4.2.1.4 in this *Response to Comments* document.

The commenter stated they completed an independent assessment of vaccine response studies with modifications to evaluation domains such as exposure assessment, outcome ascertainment, and potential confounding, however, this independent assessment conducted by ToxStrategies does not appear to be included in the comment letter or attachments. The commenter stated they determined all studies received an overall confidence rating of *deficient* or *critically deficient*, and the commenter suggested this means no studies should have qualified for POD development. However, the specific modifications made by the commenter to the study quality evaluation

criteria and rationale for why the modifications were necessary were not provided in the main comment response or in Appendix A or B. It is not clear what modifications were made to each evaluation domain and whether those modifications were scientifically appropriate. Additionally, it is unclear if at least two independent reviewers performed study quality evaluation consistent with the IRIS Handbook (USEPA, 2022a). Additionally, no protocol for the study quality evaluation was provided. Without this explanation, documentation, and transparency, the EPA is unable to comment on the ToxStrategies conclusions for vaccine response studies. Therefore, the EPA maintains its position that vaccine response should be a critical effect considered for quantitative analyses, a position that was supported by the EPA's SAB PFAS Review Panel (USEPA, 2022b).

3M Company (Doc. #1774, SBC-053298)

7. Ignoring of the totality of NHANES immune and vaccine data

The Bulka, Avula, & Fry (2021) study used NHANES data to investigate the relationship between PFAS and possible immune effects investigated eight different pathogens (cytomegalovirus (CMV), Epstein Barr virus (EBV), hepatitis virus types C and E (HCV, HEV), human immunodeficiency virus (HIV), herpes simplex virus types 1 and 2 (HSV-1, HSV-2), Toxoplasma gondii (T. gondii), and Toxocara canis and Toxocara cati (Toxocara spp.)). No relationships between PFAS and these pathogens were found, until the authors constructed a composite measure to sum across all these pathogens. However, in 2020 these same authors, using NHANES data proposed lead exposures increased the risk of CMV infection and impair immune control of the virus in young adults. The usage of the same dataset to support radically different pathways for impairment represents p-hacking which is a form of data exploitation to discover patterns which would be presented as statistically significant, when in reality, there is no underlying effect.

EPA Response: The commenter suggests the statistical approach described in Bulka, Avula, & Fry (2021) was inappropriate and may result in misleading results. The connection of the commenter's concerns about this study to the toxicity assessments for PFOA and PFOS is unclear. The EPA's evidence stream judgement of immunosuppressive effects in humans is "based on largely consistent decreases in antibody response following vaccinations (against two different infectious agents: tetanus and diphtheria) in multiple medium confidence studies in children" (USEPA, 2023f, p. 3-133). The pathogens investigated in Bulka, Avula, & Fry (2021) are unrelated to tetanus and diphtheria vaccine responses in children, and vaccines for these pathogens do not exist or are not widely available. The EPA did not quantitatively consider results presented by Bulka, Avula, & Fry (2021) in these assessments. Qualitatively, the EPA reported the mostly null results the commenter describes above. As the results are not presented as statistically significant or used quantitatively, the EPA did not conduct "p-hacking" or "exploit" the data to "discover patterns… when in reality, there is no underlying effect."

U.S. Chamber of Commerce (Doc. #1713, SBC-053363)

There are also scientific concerns related to the choice of endpoints that are used for the candidate RfDs for PFOA and PFOS. The SAB review panel, which included only one panelist with expertise in immunology,[FN107: See SAB Determination Memo and List of Candidates where expertise of candidates is described. Only one chosen panelist, Dr. DeWitt, has expertise in immunotoxicology. Documents avahttps://sab.epa.gov/ords/sab/f?p=114:18:12110592892742:::RP,18:P18_ID:2601.] supported EPA's reliance on studies which evaluated anti- tetanus and anti-diphtheria antibody concentrations. But a recent publication that reviewed the weight of evidence for immunotoxicity of PFOA and PFOS concluded that, while there was moderate evidence from animal data for immunotoxic effects, species concordance and human relevance could not be established [FN108: Gregory J. Garvey, Janet K. Anderson, Philip E. Goodrum, Kirby H. Tyndall, L. Anthony Cox, Mahin Khatami, Jorge Morales-Montor, Rita S. Schoeny, Jennifer G. Seed, Rajeev K. Tyagi, Christopher R. Kirman & Sean M. Hays (2023): Weight of evidence evaluation for chemical-induced immunotoxicity for PFOA and PFOS: findings from an independent panel of experts, Critical Reviews in Toxicology, DOI: 10.1080/10408444.2023.2194913.]. This publication, which presented an analysis and review of the most recent immunotoxicology literature, included five panelists with immunotoxicology expertise [FN109: Id. at table 3.]. That expert panel also considered the clinical relevance of using vaccine antibody titer as a measure of immunotoxicity and noted limitations of relying on this as a critical endpoint. Steenland, et al., 2020, concluded that, despite a relatively large number of studies reporting that PFOA impairs immune function, the evidence that PFOA increases risk of human infectious disease is inconsistent [FN110: Steenland K, Fletcher T, Stein CR, Bartell SM, Darrow L, Lopez-Espinosa M-J, Ryan PB, Savitz DA. (2020) Review: Evolution of Evidence on PFOA and Health Following the Assessments of the C8 Science Panel, Environment International, Volume 145, 106125.]. In addition, public commenters, and the World Health Organization, relying on additional peer reviewed publications, have noted that the value used by EPA for benchmark dose modelling is clinically meaningless [FN111: See comments submitted by Nessa Horewitch Coppinger on behalf of the 3M Company, Dec. 30, 3021, avahttps://sab.epa.gov/ords/sab/f?p=100:19:16404771425364:::RP,19:P19_ID:963 and World Health Organization (WHO) PFOS and PFOA in Drinking-water, Version for public review Sept 2022, where WHO refers to the clinical relevance of these findings as "unclear", available at: https://www.cmbg3.com/library/WHO-Draft-Drinking-Water-Document.pdf.].

EPA Response: The commenter expressed concerns regarding the immune endpoint selected as a critical effect for candidate RfDs for PFOA and PFOS. Specifically, the commenter cited a recent review on the weight of evidence for the immunotoxicity of PFOA and PFOS (Garvey et al., 2023) and stated that the clinical relevance of the endpoint of antibody response to vaccination is unclear, citing a public comment from 3M to the SAB PFAS Review Panel and the WHO Public Review Draft *Background document for deriving Guidelines for Drinking-water Quality* (WHO, 2022). Regarding the clinical relevance of the immune endpoint, please see the

EPA Response to 4.2.2.1 below, as well as the EPA responses to comment Doc. #1774, SBC-053219 and Doc. #1774, SBC-053430 in section 4.2.1.4 in this *Response to Comments* document that contained similar statements as its comments sent to the SAB. The EPA additionally notes that the WHO has since removed the cited public review draft document from the related web pages (e.g., https://www.who.int/teams/environment-climate-change-and-health/water-sanitation-and-health/chemical-hazards-in-drinking-water/per-and-polyfluoroalkyl-substances) and it is no longer publicly available. However, other global, federal, and state health agencies agree with the EPA's stance regarding the clinical relevance of the antibody response endpoint (e.g., EFSA, 2020; NTP, 2016). Notably, the draft WHO background document conclusions (WHO, 2022) conflicted with the WHO's *Guidance for Immunotoxicity Risk Assessment for Chemicals* (WHO, 2012), which stated "although data from functional immune assays (e.g. the antibody response to vaccine) are generally not available in humans, such data represent the strongest evidence of an immunosuppression." As described in Section 4.1.1.2 of both the PFOA and PFOS toxicity assessments, "results reported in animal toxicological studies are consistent with the observed immunosuppression in epidemiological studies," and support the biological relevance of this endpoint.

Regarding commenter's statement about the SAB's expertise, the EPA disagrees with commenter's implied assertion that the SAB panel was missing either depth or breadth sufficient to provide a robust peer review because the commenter identified one reviewer where immunotoxicology is listed as their highlighted subspeciality. The PFAS review panel contained a wide variety of experts, including panelists with expertise in toxicology, epidemiology, biostatistics, medicine, and economics, among other things. Additionally, the SAB itself is composed of numerous experts, including those with expertise in microbiology and drinking water, epidemiology, toxicology, economics, and medicine, among other relevant fields. In short, despite commenter's attempt to allege otherwise, the SAB is among the premier scientific review boards in the United States, populated with ample diverse expertise to provide high quality, informed, and relevant review and recommendations on the four documents the EPA sought review.

American Chemistry Council (ACC) (Doc. #1841, SBC-052925)

The Available Epidemiology Data Do Not Support an Association Between PFOA and PFOS and Antibody Response

EPA uses data from reports of decreased vaccine response among children in remote communities that may not be generalizable to other populations. The interpretation of results of the first of these studies by Timmermann et al. [FN42: Timmermann CAG et al. Concentrations of tetanus and diphtheria antibodies in vaccinated Greenlandic children aged 7–12 years exposed to marine pollutants, a cross sectional study. Environ Res 203:111712 (2022).] is confounded by exposure to other pollutants, including polychlorinated biphenyls (PCBs), and report a weak association with blood levels of PFOA and PFOS among children in Greenland. As a result, it is not an appropriate basis for developing a reference dose (RfD).

The second study by Budtz-Jorgensen and Grandjean [FN43: Budtz-Jorgensen E and Grandjean P. Application of benchmark analysis for mixed contaminant exposures: mutual adjustment of perfluoroalkyl substances associated with immunotoxicity. PLoS ONE 13:e0205388 (2018).] reports two findings from the study of diphtheria and tetanus antibody concentrations associations among a unique, remote cohort of children of the Faroe Islands –

• An association between prenatal exposure to PFOA/PFOS and antibody concentrations at 5 years of age, and

• An association between PFOA/PFOS serum concentrations at age 5 and antibody concentrations at age 7. [FN44: The draft approaches select the benchmark dose modeling results for the serum levels at age 5 and antibody levels at age 7 from the cohort of children born between 1997-2000 to calculate the reference doses.]

In an earlier publication by Grandjean et al. (2012), [FN45: Grandjean P et al. Serum vaccine antibody concentrations in children exposed to perfluorinated compounds. J Amer Med Assn 307(4):391-397 (2012).] however, this research group did not observe an association between maternal PFOA/PFOS serum concentrations and antibody concentrations at age 5 in a cohort of children born between 1997 and 2000. Although the researchers reported an association in a cohort of Faroe Islands children born from 2007 and 2009, serum concentrations were lower than in the earlier cohort (see Table 3).

Table 3. Comparison of Serum Concentrations at Birth and 60 months in the Studies of Faroe Islands Children

Table 3. Comparison of Serum Concentrations at Birth and 60 months in the Studies of Faroe Islands Children

	Median Concentration (Interquartile Range)			
	1997-2000 Cohort[a]		2007-2009 Cohort[b]	
	At birth	At 60 months	At birth	At 60 months
PFOS (ng/ml)	27.3 (23.2,33.1)	16.7 (13.5,21.1)	n/a	4.7 (3.5,6.3)
PFOA	3.20 (2.6,4.0)	4.1 (3.3,4.9)	n/a	2.2 (1.8,2.8)

[a] Table 2, Grandjean *et al.* 2012; [b] Table 1, Grandjean *et al.* 2017a[46]

[Table 3: See Docket ID EPA-HQ-OW-2022-0114-1841] [FN46: Grandjean P et al. Estimated exposures to perfluorinated compounds in infancy predict antibody concentrations at age 5 years. J Immuno 14(1):188-195 (2017a). Maternal serum concentrations are not provided.]

Among 7-year olds, the Faroe Islands researchers did not find an association between serum concentrations and antibody levels at 7 after excluding children suspected of receiving additional

antibodies (i.e., no booster, ER visit, or unexplained antibody increase). [FN47: Grandjean P et al. Serum vaccine antibody concentrations in adolescents exposed to perfluorinated compounds. Environ Health Perspect 125:077018 (2017b).] Although the 2012 publication reports an association between serum levels of PFOA at age 5 and tetanus antibody concentrations at age 7, [FN48: No association is observed between PFOS serum concentrations at age 5 and diphtheria antibody concentrations at age 7, after adjusting for the antibody concentration at age 5.] the analysis does not control for children receiving additional antibodies between ages 5 and 7. Given the results of the prior analysis, this would appear to be a significant oversight that raises additional questions about the broad conclusion that exposure to PFOA or PFOS reduces vaccine response in children.

A recent independent, international expert panel was engaged using a double-blind process to review the available evidence relating to PFOA and/or PFOS exposure and immunotoxicity (Garvey et al. 2023). [FN49: Garvey GJ et al. Weight of evidence evaluation for chemical-induced immunotoxicity for PFOA and PFOS: findings from an independent panel of experts. Crit Rev Toxicol 53(1):34-51 (2023).] The panel concluded that while there may be some evidence that PFOA and PFOS are immunotoxic based primarily on laboratory animal studies, species concordance and human relevance cannot be established. Moreover, they also concluded that the human data, and specifically the use of reduced vaccine antibody titers as a critical effect, are inappropriate for use in deriving toxicity values and regulatory standards. This conclusion is consistent with other agency evaluations. [FN50: COT 2022; Agency for Toxic Substances and Disease Registry (ATDSR). Toxicological Profile for Perfluoroalkyls. US Department of Health and Human Services (May 2021). (ATSDR PFAS Tox Profile)]

The Evidence for Increased Infection Rates Among Children is Not Consistent

In its analysis, EPA suggests that a decrease in antibody concentrations may reduce the prevention of diphtheria and tetanus in children. Results of associations between PFOA and PFOS exposure and childhood infection are mixed, however, with studies reporting both increased and decreased associations with reported infections. [FN51: Steenland K et al. Review: Evolution of evidence on PFOA and health following the assessments of the C8 Science Panel. Environ Int 145: 106125 (2020).] As a result, NTP concluded that there is low confidence that exposure to either substance is associated with an increased incidence of infectious disease or a lower ability to resist or respond to infectious disease. [FN52: NTP. Immunotoxicity Associated with Exposure to Perfluorooctanoic acid or Perfluorooctane Sulfonate. NTP Monograph. US Department of Health and Human Services. (September 2016)]

The epidemiological evidence for an association between PFOA and PFOS exposure and hypersensitivity and autoimmune disease is also mixed. Studies that observed significant associations with “ever” or “current” asthma are seen primarily in sex- or age-specific subgroups but are null or insignificant in whole study analyses. For allergy and eczema outcomes, results were inconsistent across studies. Studies of PFOS exposure and autoimmune condition in humans are limited, and the results from studies of PFOA exposure and human autoimmune disease are mixed. While Steenland et al. report an association with ulcerative colitis, [FN53:

Steenland K et al. Ulcerative colitis and perfluorooctanoic acid (PFOA) in a highly exposed population of community residents and workers in the mid-Ohio valley. Environ Health Perspect 121: 900-905 (2013).] the analysis does not adequately control for confounding factors such as gastrointestinal infection and family history. [FN54: http://www.c8sciencepanel.org/study.html.]

EPA Response: The commenter raised concerns with the studies the EPA reviewed and considered in the determination of decreased antibody response in children as a critical effect. Please see the EPA Response to 4.2.2.1 below. Additionally, the commenter stated that Timmerman et al. (2021) was not appropriate for developing an RfD due to potential confounding by other pollutants. The EPA disagrees with this statement. While it is true there are other co-occurring exposures to organic pollutants in this population, as is the case for all studies in humans, the study authors still concluded that they "found decreased diphtheria concentrations after vaccination with increasing PFAS exposure, and higher serum concentrations of PFAS were associated with increased odds of not being protected against diphtheria after vaccination" (Timmerman, 2021). The EPA noted in Appendix E of the toxicity assessments for PFOA and PFOS that Timmerman et al., (2021) was chosen for comparison purposes as it represented another population—children from Greenland—compared to studies conducted in the Faroe Islands (USEPA, 2023b; USEPA, 2023c).

The commenter also raised concerns about the use of Budtz-Jorgensen (2018) for developing an RfD, citing the study setting, lack of significant findings in prior publications (i.e., Grandjean, 2012). Regarding the consistency of the antibody response epidemiological evidence base and epidemiological evidence reporting associations between PFOA or PFOS and other immune effects, please see the EPA response to comment Doc. #1774, SBC-053219 and Doc. #1774, SBC-053430 in section 4.2.1.4 of this *Response to Comments* document, and section 4.2.2.3.1 of the EPA response in this *Response to Comments* document. The commenter did not provide new rationale that the EPA had not already considered when selecting the health outcome-specific RfD for immune effects (see sections 3 and 4 of the toxicity assessments; USEPA, 2024d; USEPA, 2024c).

Regarding reasons why the EPA's conclusions may differ from those of other health agencies, please see the EPA Response to 4.2.6.

Mike Pettit (Doc. #1542, SBC-052839)

Immune effects: pg 268 reads "Some evidence suggests a relationship between PFOA exposure and immunosuppression; epidemiology studies showed suppression of at least one measure of the antibody response for tetanus and diphtheria among people with higher prenatal, childhood, and adult serum concentrations of PFOA. It is less clear whether PFOA exposure impacts antibody response to vaccinations other than tetanus and diphtheria. Epidemiology evidence suggests that children with preexisting immunological conditions are particularly susceptible to immunosuppression associated with PFOA exposure. Available studies supported an association between PFOS exposure and immunosuppression in children, where increased PFOS serum

levels were associated with decreased antibody production. However, the association between PFOS exposure and immunosuppression was not apparent in adults. Other potential associations with PFOS exposure with a high degree of uncertainty included asthma and infectious diseases (e.g., the common cold, lower respiratory tract infections, pneumonia, bronchitis, ear infections). Animal toxicology study evidence suggested that PFOA or PFOS exposure results in effects similarly indicating immune suppression, such as reduced response of immune cells."

Here there is a problematic factor- the immune system is a very complex machine that is not yet even close to being fully understood. As such it makes it difficult to accurately pinpoint if PFAS is ever truly interacting with the immune system or not, or if there is another confounding factor being measured. The high level of uncertainty indicated in the actual papers also points out that these studies do not take these potentially confounding factors into account. The levels of suppression are not spelled out in any way and what does higher serum levels entail? What are the levels? Are there preexisting conditions that need to be addressed. The sentence that children with immunecompromised systems are sensitive to PFOA is ridiculous. Obviously those with weak and compromised immune systems will be detected as weak and compromised when studied. Again, the liberal usage of the term 'suggestive' is folly. These values can be quantified with proper procedures and studies.

EPA Response: For concerns regarding uncertainty in the antibody response evidence base and consideration of confounding factors, please see the EPA response to comment Doc. #1774, SBC-053219 and Doc. #1774, SBC-053430 in section 4.2.1.4 in this *Response to Comments* document and section 4.2.2.3.1 of the EPA response in this *Response to Comments* document.

The commenter suggested it is too difficult to determine the effect of PFOA or PFOS on the immune system as it is too complex and "is not yet even close to being fully understood." The EPA disagrees the immune system is too complex to determine an effect. While there are still areas of research in immunology, it is a well-established field with a wealth of literature that has been applied in both medical and public health contexts, including the use of developmental immunotoxicology data for risk assessment (Dietert, 2008). The EPA identified and synthesized evidence from controlled animal toxicology studies and mechanistic studies which provided support for determining reduced antibody response in children as a critical effect (USEPA, 2023f, USEPA, 2023a, Sec. 3.4.2.2 and Sec. 3.4.2.3). This includes mechanistic evidence (NTP, 2016) demonstrating T-cell-dependent and T-cell-independent responses being reduced in mice treated with PFOA, suggesting a possible explanation for decreased antibody response in humans (USEPA, 2023f). Recent evidence from mechanistic studies also provide evidence for "PFOS-mediated suppression of adaptive immune responses includ[ing] PFOS-mediated effects on TH1/TH2-type cytokines and IgE titers in response to allergens in mice and humans (Zhong, 2016, 3748828; Zhu, 2016, 3360105), glycosylation of immunoglobulins in humans (Liu, 2020, 6833599), and lymphocyte toxicity *in vitro* (Zarei, 2018, 5079848)" (USEPA, 2023a, Sec. 3.4.2.3.2.7).

The commenter claimed the "levels of suppression" and what this means are not communicated. The EPA disagrees with this statement and directs the commenter to section 4.2.2.1 of the EPA response in this *Response to Comments* document for additional information on RfD derivation, as well as Appendix E (USEPA, 2023b; USEPA, 2023c, Sec. E.1.1.1) and Section 4 of the toxicity assessments (USEPA, 2023f; USEPA, 2023a) for discussion on setting a benchmark response (BMR) in accordance with biological and statistical guidance provided in the EPA's *Benchmark Dose Technical Guidance* (USEPA, 2012).

The commenter raised concerns about considerations for immunosuppressed or other pre-existing conditions. As mandated by SDWA, the EPA must consider sensitive subpopulations in its regulatory decisions. For instance, when making regulatory determinations, the Administrator is directed to prioritize contaminants that may impact sensitive subpopulations (see 1412(b)(1)(C)). Additionally, when conducting its health risk and cost analysis, the EPA shall consider "The effects of the contaminant on the general population and on groups within the general population such as infants, children, pregnant women, the elderly, individuals with a history of serious illness, or other subpopulations that are identified as likely to be at greater risk of adverse health effects due to exposure to contaminants in drinking water than the general population" (See SDWA 1412(b)(3)(C)(V)). As required under the SDWA, the EPA considered effects on potentially sensitive populations and subsequently recognized immunocompromised children as a population of concern. While it may be obvious to the commenter that immunocompromised individuals may be particularly sensitive to the immune effects associated with PFOA and PFOS exposure, the EPA attempts to ensure that the majority of the U.S. population can understand the various analyses and considerations that underly this rulemaking.

4.2.1.5 Consideration of Increased Serum ALT as a Critical Effect

3M Company (Doc. #1774, SBC-053217)

iv. EPA's assessment of liver effects is was not performed consistent with best practices.

EPA's assessment of liver effects of exposure to PFOA and PFOS is inconsistent with its own scientists' and the SAB's conclusions and again reflects EPA's failure to engage in a proper systematic review and evidence assessment process. As part of the hazard characterization and dose-response step, the IRIS Handbook states that EPA should consider the dose-response pattern in the relevant dose range and relevance of specific health outcomes in humans. In contrast to this recommendation, EPA cites animal studies showing liver effects which involve mechanisms of action with questionable relevance to humans, such as pathways moderated by peroxisome proliferator-activated receptor-alpha ("PPARα"). EPA also did not consider EFSA (2020), which noted there is evidence for elevated ALT due to PFOA exposure, but the adversity of this effect is uncertain because of the low magnitude of increases and no associations with liver disease. EPA even acknowledges that studies "have questioned the biological significance of relatively small increases in serum ALT (i.e., less than 2-fold) reported in animal toxicological studies (Hall. et al. 2012)." For PFOA and PFOS, EPA fails to characterize the biological relevance of changes in ALT or other liver biomarkers in the context of quantitative clinical outcomes. SAB similarly

noted that "the limited available information does not demonstrate an increase in liver disease" (USEPA SAB 2022).

As an example of its failures in conducting systematic review and assessing study quality, EPA inappropriately based its candidate PFOS RfD for elevated ALT on a study by Nian et al., (2019). This was a cross-sectional study from China that reported a 4.1 percent change (95% CI: 0.6, 7.7) in ALT for every 1 ng-mL increase in PFOS. Excluding individuals who were taking medications, this percent change was reduced to 3.8 which was not statistically significant (95% CI: -0.2, 7.8). Confounding variables were also not adequately controlled as most were described as binary (yes/no) which included alcohol, smoking and diet, which limits quantitative assessment. In addition, confounding from other PFAS were not adjusted for in the analysis of PFOS and PFOA. In EPA's section on Study Evaluation for Epidemiology Studies of PFOS and Hepatic Effects (page 3-25), EPA states that the Nian et al., (2019) approach to study participant selection and recruitment was not described in the paper. However, EPA still rates participant selection as "adequate." Given this information was not provided, EPA should have rated participant selection as "inadequate" based on its own criteria.

EPA Response: Regarding the commenters' statement about mechanisms of action in animal studies of liver effects, the non-cancer hepatic mechanistic evidence for PFOA is discussed in Sections 3.4.1.3 and 3.4.1.4 of the toxicity assessment (USEPA, 2024d; USEPA, 2024c; USEPA, 2023f; USEPA, 2023a) and focuses on several mechanisms such as nuclear receptor activation, lipid metabolism, transport, and storage, hormone function and response, xenobiotic metabolism, cell viability, growth, and fate, inflammation and immune response, and oxidative stress and antioxidant activity. While some of these mechanisms do involve PPARα, many of them do not involve peroxisome proliferator-activated receptors. The evidence also suggests a role for PPARα-independent pathways in the MOA for noncancer liver effects of PFOA. PFOA has been shown to activate a number of other nuclear receptors, including PPARγ, CAR/PXR, ERα, and HNF4α, which play an important role in liver homeostasis and have been implicated in liver dysfunction. In addition to the abundance of evidence related to hepatic nuclear receptors, PFOA also alters apoptosis and cell proliferation in the liver, indicating a cytotoxic mechanism of action. Further, the relevance of PPARα and species-specific differences in PPARα have already been addressed by the EPA in Section 3.4.1.4 of the draft toxicity assessments, which was available at the time of rule proposal (USEPA, 2023f; USEPA, 2023a. The molecular or cellular initiating events that do not involve PPARα and have been observed in vivo and in vitro are described in the mechanistic section of the Evidence Profile Table in 3.4.1.4 (i.e., increased apoptosis through a cascade of mechanisms, inflammation of the liver, induction of oxidative stress, and indirect evidence of alternative pathways following observations in knockout or humanized PPARα mice).

For hepatic cancer effects, in the absence of a clear MOA for PFOS carcinogenicity, the EPA considered all possible MOAs when evaluating the hepatic tumor evidence in rodents. The EPA considered the evidence for several potential underlying mechanisms and modes of action in addition to PPARα activation, such as pathways involving other nuclear receptors (e.g., CAR)

and cytotoxicity. The EPA mapped the available mechanistic evidence collected in rodent studies for all plausible MOAs in Section 3.5.4.2 Mode of Action for Hepatic Tumors. Evidence was identified for at least one key event in multiple MOAs (e.g., altered gene expression relevant to CAR activation, cytotoxicity, altered serum enzymes), while evidence was not identified for *all* key events in any MOA, including PPARα activation (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c).

Second, to increase transparency, the EPA has added additional detail regarding the relevance of ALT to liver function and clinical disease in Section 4.1.1.1 of the PFOA and PFOS toxicity assessments (USEPA, 2024d; USEPA, 2024c). Further, the SAB PFAS Panel specifically supported the use of increased ALT as a critical endpoint (USEPA, 2022b). Regarding EFSA (2020), the authors' statement about the magnitude of association observed for ALT addresses only epidemiology studies examining the PFOS-ALT association. The authors did not draw conclusions about the clinical impact of small magnitude changes in ALT and incidence of liver disease. Studies examining the association between PFOS and liver disease were limited and primarily of *low* confidence (USEPA, 2023a, Sec. 3.4.1.4). Please also see section 4.2.6 of the EPA response in this *Response to Comments* document for additional discussion related to other agency assessments.

Regarding the relevance of small increases in serum ALT reported in animal toxicology studies, results can be supported by evidence of histopathological liver damage. This was the case for both PFOA and PFOS, for which animal toxicological studies reported increased incidence of liver cell death and necrosis (Section 3.4.1.2, USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024b), confirming the potential relevance of relatively small changes in serum enzymes such as ALT. Regarding the quoted statement from USEPA SAB (2022b), the lack of *high* confidence studies examining PFOA and PFOS and liver disease outcomes does not equate to a known lack of association. The EPA further notes that in the same document, USEPA (2022b) acknowledged the public health importance of ALT increases associated with PFOA and PFOS exposure and recommended that the EPA include ALT as an endpoint for RfD derivation (p. 28, "The Panel recommends the use of ALT as endpoint in light of the numerous studies in the literature support an association between slight elevations in ALT and increased risk of morbidity and/or mortality"). Additional discussion related to the EPA's consideration of SAB recommendations is available in section 4.1.3 of the EPA response in this *Response to Comments* document. Please see section 4.1.2 of the EPA response in this *Response to Comments* document for discussion related to the use of agency guidance in the PFOA and PFOS toxicity assessments.

Third, the EPA disagrees that the use of Nian et al. (2019) for the PFOS RfD was inappropriate. The EPA provided information on the process for selecting studies for RfD development in Appendix A, Section A.1.11.1. These criteria are related to but distinct from the study quality evaluation process in which studies are evaluated for potential risk of bias due to the factors detailed by the commenter. In particular, studies that have been rated *high* or *medium* confidence during study quality evaluation such as Nian et al. (2019) are preferred, but other criteria such as suitability for modeling and data available are also considered when selecting a study for POD

derivation. Considering all of these criteria, Nian et al. (2019) was among the studies best suited for RfD development. In response to these public comments, the EPA has added additional rationale for POD study selection in section 4.1.1 of the final toxicity assessments (USEPA, 2024d; USEPA, 2024c).

Finally, the EPA disagrees that Nian et al. (2019) should not have been rated as "adequate" under the participant selection domain in study quality evaluation. As described in Appendix A, Section A. 1.7.1.1, a study merits a participant selection rating of "adequate" when there is enough information regarding the selection process that the reviewers judge there is no serious risk of bias. While some aspects of the recruitment process for government employees included in the study population were not described, study quality evaluators judged that selection bias was "unlikely based on available information," consistent with the criteria for an "adequate" rating.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053369)

Similar concerns, regarding the adversity of the chosen critical effect, arise with EPA's choice of ALT as an RfD endpoint for PFOA and PFOS. In the Draft Public Comment Assessment, in discussing the association between PFOS and ALT, EPA states:

However, the associations were not large in magnitude, and it is unclear whether the observed changes are clinically adverse. Evidence for other liver enzymes and in children and adolescents is less consistent. Results for functional measures of liver toxicity, specifically histology results, are mixed. There is some indication of higher risk of liver disease with higher exposure, coherent with the liver enzyme findings, but there is inconsistency for lobular inflammation among the two available studies, which decreases certainty [FN119: See Public Comment Draft Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) in in Drinking Water (Public Comment Draft Assessments), at page 3-6e at: https://www.regulations.gov/document/EPA-HQ-OW-2022-0114-0034.].

EPA further states, "It is not possible to rule out potential confounding across PFAS with this evidence, but there is also no evidence that confounding can explain the observed associations." EPA's key supporting document for the proposed rule does not provide strong support for this chosen critical endpoint.

EPA Response: The commenter stated that the choice of ALT as a critical endpoint is not strongly justified. To support this point, the commenter raised concerns over whether observed changes in ALT are clinically significant, as well as over potential confounding by co-occurring PFAS. The EPA disagrees with these comments. Please refer to the EPA Response to 4.2.2.1 and the EPA Response to SBC-053217.

Additionally, the EPA disagrees that changes in ALT associated with PFOS or PFOA are not clinically relevant. As previous research on lead exposure has found, although small changes in an outcome (e.g., ALT) at the individual level may or may not reach a level considered clinically significant, such small changes can result in substantial health impacts at the

population level (Gilbert and Weiss, 2006). As described in Section 4.1.1.1 of the PFOA and PFOS Assessments, evidence from both epidemiologic and toxicologic studies indicates that elevated serum ALT is associated with clinical liver disease. The EPA also notes that potential confounding by other PFAS co-exposures was considered during study quality evaluation and as part of the overall evidence stream judgement (USEPA, 2023, Sec. 3.4.4.1.2 and Sec. 3.4.4.4). The EPA maintains there is no consensus on best practices to account for potential confounding by multiple, concurrent PFAS exposures. For further discussion of this issue, please see the EPA response to similar comments in Doc. #1774, SBC-053211 and Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-052927)

The Human Evidence for an Association Between Liver Disease and PFOA and PFOS is Lacking

EPA's estimate of potential risks of liver effects related to PFOA and PFOS exposure is based on findings of increased liver enzymes (primarily alanine aminotransferase, or ALT) in epidemiology studies. Although elevation of liver serum biomarkers in humans may be an indication of liver injury, it is not as specific as histological findings or functional tests for liver disease. The reported increase was small, however, and not considered indicative of hepatocellular injury. In analyzing liver enzymes in nearly 50,000 community residents and workers in the C8 Science Panel survey, the Panel noted the while the increase in enzyme levels may suggest small shifts in liver function, they are mainly within the normal physiologic range. [FN59: C8 Study Panel. Probable Link Evaluation for Liver 2012). http://www.c8sciencepanel.org/pdfs/Probable_Link_C8_Liver_29Oct2012.pdf] Based on its analysis, the Panel concluded that "there was no evidence of a positive association between liver disease and estimated PFOA exposure." While the epidemiological data are not as robust for PFOS, the information available on functional measures of liver injury is conflicting.

Although EPA initially determined that the data were not sufficient to support development of an RfD for liver health effects, [FN60: USEPA Draft PFOS MCLG Approaches 2021, at 308.] its decision to develop an RfD based on the liver enzyme data appears based on the review by EPA's Science Advisory Board (SAB). [FN61: USEPA SAB. Review of EPA' Analyses to Support EPA's National Primary Water Rulemaking for PFAS. EPA-SAB- 22-008 (2022). (USEPA SAB Review)] However, the SAB recommendation to consider changes in ALT is based on consistency with EPA's approach to other health endpoints. The Board explains its recommendation as follows -

The Panel noted that, although the magnitude of PfOA and/or PFOS's effect on ALT may not be large, the same may also be true for the magnitude of the PFOA and/or PFOS's effects on other human health endpoints such as, increased cholesterol and decreased birth weight. As such, if a [point of departure] is not developed for the ALT endpoint, an explanation should be provided as to why the magnitude of the effect was not sufficient for ALT but was sufficient for other effects of similar magnitude. [FN62: Ibid, at 24.]

In fact, the Board appears to be commenting on the weakness of data supporting several of the endpoints selected by EPA, rather than concluding that the liver data are sufficiently strong. Although the SAB points to EPA guidance on RfD development, the available data for PFOA and PFOS do not support a conclusion that the modest increase in ALT is a precursor to an adverse effect. The Board also provides a number of references on ALT, but as EPA correctly notes, none are specific to PFOA and PFOS. [FN63: USEPA. EPA Response to Final Science Advisory Board Recommendations (August 2022) on Four Draft Support Documents for the EPA's Proposed PFAS National Primary Drinking Water Regulation. Office of Water (2023). (USEPA Response to SAB)] In responding to the SAB, EPA provides no new evidence of liver disease. Rather the Agency explains how it conducted BMD modeling for the ALT endpoint. [FN64: EPA BMD analysis includes a BMR of 5 percent, despite the lack of evidence of liver disease and the recommendation of the BMD guideline to use 10 percent.]

As with the immune and CVD endpoints, EPA's analysis of effects focuses on a that is has not been linked to . In addressing this type of situation in updating its 2022 guidance for developing assessments under the Integrated Risk Information System, EPA notes that "[i]f the evidence base primarily includes outcomes or endpoints that are indirect measures (e.g., biomarkers) of the unit of analysis, certainty (for that unit of analysis) is typically decreased" particularly for "findings that have an unclear linkage to an apical or clinical (adverse) outcome." [FN65: USEPA. ORD Staff Handbook for Developing IRIS Assessment. EPA/600/R-22/268. Office of Research and Development, Washington, DC (2022). (USEPA IRIS Handbook)] EPA has chosen to rely on indirect measures in developing RfDs for immune, CVD, and liver effects of PFOA and PFOS – ignoring the weight of evidence available from human and animals studies in direct conflict with the SDWA requirement to use "best available, per-reviewed science." [FN66: 42 U.S.C. Section 300g-1(b)(3)(A).]

EPA Response: The commenter states that the information available on functional measures of liver injury is conflicting for PFOA and PFOS. The EPA disagrees with the statement and points to the EPA response to comment Doc. #1774, SBC-053217 in section 4.2.1.5 in this *Response to Comments* document and Section 3.4.3.4 of the toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c). These sections also describe how the EPA included evidence from human and animals in the evidence integration judgments, in contrast to the commenter's claims. The commenter is additionally misinterpreting the selected quote by the SAB PFAS Review Panel and ignoring the SAB's strong statement that, the "EPA should use Alanine Aminotransferase (ALT) as an endpoint in light of the numerous studies in the literature that support an association between slight elevations in ALT and increased risk of morbidity and/or mortality" (USEPA, 2022b). The EPA provides adequate rationale for consideration of the endpoint of increased ALT for dose-response analysis in Sections 3.4 and 4.1 of the toxicity assessments.

The commenter also states that has chosen to rely on indirect measures in developing RfDs for immune, CVD, and liver effects of PFOA and PFOS. The EPA disagrees with the implication

that the critical effects identified by the EPA are not biologically relevant. Please see section 4.2.2 of the EPA response in this *Response to Comments* document.

Mike Pettit (Doc. #1542, SBC-052838)

Liver effects: pg 268 reads "Epidemiology data provides consistent evidence of a positive association between PFOS/PFOA exposure and ALT levels in adults. Studies of adults showed consistent evidence of a positive association between PFOA exposure and elevated ALT levels at both high exposure levels and exposure levels typical of the general population. There is also consistent epidemiology evidence of associations between PFOS and elevated ALT levels, although the associations observed were not large in magnitude. Study results showed inconsistent evidence on whether the observed changes led to changes in specific liver disease. Toxicology studies on the impact of PFOS exposure on ALT in rodents also reported increases in ALT and other liver enzyme levels in rodents, though these increases were modest."

The mechanism by which PFOS may affect the liver is not clearly understood. Some studies have suggested that PFOS may cause liver effects by disrupting lipid metabolism, while others have suggested that PFOS may directly damage liver cells. It is also important to note there is a potential for bias in some of the studies linking PFOS to liver effects. For example, some studies may have included individuals with preexisting liver disease, which could bias the results. Additionally, some studies may have used non-standardized methods for assessing liver damage, which could lead to inaccurate or inconsistent results

EPA Response: The commenter stated that the mechanisms of action by which PFOS induces hepatic effects are unclear. The EPA agrees that there are several potential mechanisms by which PFOS may induce hepatic effects and there is not enough evidence to definitively conclude that one MOA is responsible for the reported hepatotoxicity. The mechanistic evidence supporting hepatic effects in humans and animals is available in Section 3.4.1.3 of the PFOS toxicity assessment (USEPA, 2024c; USEPA, 2023a). The EPA additionally notes that mechanistic evidence is generally used to support the relevance of animal effects to humans and provide biological plausibility for evidence integration judgments but known mechanisms of action are not required for hazard identification or characterization (USEPA, 2022a).

As described in Section 3.4.1.4 of the PFOS toxicity assessment, the coherent evidence across controlled laboratory studies in animals and the epidemiological studies in humans supports the EPA's conclusions that PFOS exposure is likely to cause hepatotoxicity in humans (USEPA, 2024c; USEPA, 2023a). The consistent evidence across studies in different species and populations with varying exposure histories reduces the potential uncertainties that may be raised due to individual study limitations *(e.g., non-standard methods).*

4.2.1.6 Consideration of Additional Endpoints

Silent Spring Institute (Doc. #1784, SBC-045800)

In its summary of noncancer health effects for PFOA and PFOS, EPA determined that oral exposure to PFOA and PFOS is associated with hepatic, immune, cardiovascular, and developmental effects. Beyond those endpoints, EPA's discussion of developmental effects misses impairments to mammary gland development and lactation.[REF2: Kay JE, Cardona B, Rudel RA, et al. Chemical Effects on Breast Development, Function, and Cancer Risk: Existing Knowledge and New Opportunities. Curr Environ Health Rep. 2022;9(4):535-562.] Current evidence from studies with rodent models demonstrate that low- dose PFOA exposures can lead to reduced mammary differentiation and altered milk protein gene expression.[REF11: Macon MB, Fenton SE. Endocrine disruptors and the breast: Early life effects and later life disease. J Mammary Gland Biol Neoplasia. 2013;18(1):43-61.; REF12: Tucker DK, Macon MB, Strynar MJ, Dagnino S, Andersen E, Fenton SE. The mammary gland is a sensitive pubertal target in CD-1 and C57Bl/6 mice following perinatal perfluorooctanoic acid (PFOA) exposure. Repro Toxicol. 2015;54:26-36.; REF13: White SS, Stanko JP, Kato K, Calafat AM, Hines EP, Fenton SE. Gestational and chronic low-dose PFOA exposures and mammary gland growth and differentiation in three generations of CD-1 mice. Environ Health Perspect. 2011;119(8):1070-1076.; REF14: White SS, Calafat AM, Kuklenyik Z, et al. Gestational PFOA Exposure of Mice is Associated with Altered Mammary Gland Development in Dams and Female Offspring. Toxicol Sci. 2006; 96(1):133-144.] We note that EPA derived a human equivalent dose reference dose (RfD) of 15 ng/kg- day based on impaired mammary gland development in its plan to develop the PFOA MCL.[REF15: U.S. EPA (U.S. Environmental Protection Agency). External Peer Review Draft: Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) (CASRN 335-67-1) in Drinking Water. EPA, Office of Water, Washington, DC; 2021.] This was a similar conclusion from the Texas Commission on Environmental Quality, which used a study of impaired mammary gland as its critical study in developing its 2016 Protective Concentration Level, deriving a RfD of 12 ng/kg-day.[REF16: TCEQ (Texas Commission on Environmental Quality). Toxicological Evaluation of Perfluoro Compounds. 2016.] In order to comprehensively describe health effects of PFAS chemicals, EPA's risk assessment should include a description of the mammary gland effects along with the other endpoints and demonstrate that the proposed risk assessment is protective for all of them. A similar discussion, for example, is included in the New Jersey Department of Environmental Protection (NJDEP) Health-Based MCL determination. NJDEP noted that delayed mammary gland development, along with increased liver weight, were the two most sensitive non-carcinogenic endpoints associated with PFOA exposure.[REF17: New Jersey Department of Environmental Protection. Health-Based Maximum Contaminant Level Support Document: Perfluorooctanoic Acid (PFOA). Trenton, NJ: New Jersey Drinking Water Quality Institute, Health Effects Subcommittee; 2017.] NJDEP concluded that the target serum concentration to be protective of delayed mammary gland development was below the median serum PFOA level in the general population and would correspond to an RfD of 0.11 ng/kg-day.[REF17: New Jersey Department of Environmental Protection. Health-Based Maximum Contaminant Level Support Document: Perfluorooctanoic Acid (PFOA). Trenton, NJ: New Jersey Drinking Water Quality Institute, Health Effects Subcommittee; 2017.] While NJDEP's

recommended MCL did not directly incorporate these mammary gland effects, NJDEP applied an extra uncertainty factor to account for this and other sensitive endpoints.

Evidence of impaired mammary gland development after PFOA exposure in rodent studies is consistent with findings in human studies that document effects on lactation, and potentially increased breast cancer risk.[REF2: Kay JE, Cardona B, Rudel RA, et al. Chemical Effects on Breast Development, Function, and Cancer Risk: Existing Knowledge and New Opportunities. Curr Environ Health Rep. 2022;9(4):535-562.] As noted by researchers at the Silent Spring Institute and others, altered mammary gland development may impair lactation and increase breast cancer susceptibility later in life.[REF1: National Academies of Sciences, Engineering, and Medicine. Guidance on PFAS Exposure, Testing, and Clinical Follow-Up. Washington, DC: The National Academies Press; 2022.; REF2: Kay JE, Cardona B, Rudel RA, et al. Chemical Effects on Breast Development, Function, and Cancer Risk: Existing Knowledge and New Opportunities. Curr Environ Health Rep. 2022;9(4):535-562. ; REF11: Macon MB, Fenton SE. Endocrine disruptors and the breast: Early life effects and later life disease. J Mammary Gland Biol Neoplasia. 2013;18(1):43-61.; REF18: Rudel RA, Fenton SE, Ackerman JM, Euling SY, Makris SL. Environmental exposures and mammary gland development: State of the science, public health implications, and research recommendations. Environ Health Perspect. 2011;119(8):1053-1061.] In humans, PFOA, PFOS, PFNA, and PFDA concentrations in serum were associated with shorter duration of breastfeeding in a cohort of mothers in the Faroe Islands[REF19: Timmermann CAG, Budtz-Jorgensen E, Petersen MS, et al. Shorter duration of breastfeeding at elevated exposures to perfluoroalkyl substances. Repro Toxicol. 2017;68:164-170.] and elevated serum PFOA was associated with early termination of breastfeeding in a cohort of U.S. mothers.[REF20: Romano ME, Xu Y, Calafat AM, et al. Maternal serum perfluoroalkyl substances during pregnancy and duration of breastfeeding. Environ Res. 2016;149:239-246.]

EPA Response: The commenter recommended the EPA reconsider its decision to exclude the critical effect of mammary gland development in rodents when selecting endpoints to serve as the basis of candidate RfDs for the developmental health outcome based on conclusions from other agency assessments. In response to these comments, the EPA reevaluated the evidence underlying this endpoint for both PFOA and PFOS. The EPA did not identify studies reporting on mammary gland development in animal models administered PFOS. For PFOA, the EPA has maintained the position the agency took when developing the 2016 HESD (USEPA, 2016a) and the public comment draft toxicity assessment for PFOA (USEPA, 2023f). More specifically, the EPA previously stated, “there is uncertainty related to the functional impact of this endpoint,” given a lack of evidence correlating mammary duct branching patterns and decreased ability to support pup growth during lactation (USEPA, 2016b). No new studies in animal models have been published since 2016 that would contradict this conclusion. In contrast to the commenter’s claims, the EPA did “include a description of the mammary gland effects along with the other endpoints” in Section 3.4.4.2.7 (“Mammary Gland Development”) of the PFOA toxicity assessment (USEPA, 2023f). As there was no evidence from the available animal literature supporting the hypothesis that altered mammary gland development results in decreased

lactational efficiency and subsequent reductions in offspring growth or survival, the EPA did not consider epidemiological studies reporting reduced breastfeeding duration, which was categorized under the non-priority health outcome of Reproductive effects, for POD derivation. The EPA instead focused on health outcomes that were coherent across epidemiological and animal toxicological studies (e.g., reduced offspring birthweight), and that have supporting evidence of adversity (e.g., reduced offspring survival).

The EPA additionally notes, regarding the commenter's request that the EPA "demonstrate that the proposed risk assessment is protective" of mammary gland effects, that an MCLG of zero based on cancer effects is the most protective value possible. Please see section 4.2.6 of the EPA response in this *Response to Comments* document for additional discussion related to how the EPA considered other agency assessments.

4.2.2 Toxicity Value Derivation

Summary of Major Public Comments and EPA Responses

The EPA requested comment on the derivation of draft toxicity values (i.e., RfDs and CSFs) for PFOA and PFOS. Many commenters supported the draft toxicity values derived for PFOA and PFOS. Other commenters noted uncertainties surrounding the extrapolation of data from animal toxicological studies to support the derivation of toxicity values for human exposure. A few of these commenters also noted the importance of epidemiological data to support quantitative dose-response assessments and MCLG derivation. In contrast, one commenter critiqued the EPA for relying on epidemiological data and the commenter claimed the EPA was "ignoring" high confidence data from animal studies. Some commenters provided comments specific to the RfDs or CSFs, further described below.

The EPA agrees that, when warranted by the chemical-specific database, the agency is supported in its use of epidemiological data for the derivation of toxicity values over data from animal toxicological studies because this approach eliminates uncertainties related to interspecies extrapolation (USEPA, 2022a). The EPA agrees with commenters who state the databases for PFOA and PFOS warrant this approach because there are numerous epidemiological studies of *high* or *medium* confidence for each critical effect that showed consistent direction of effect in multiple human populations, as well as coherence with evidence presented in animal toxicological studies (see the evidence profile tables and the weight of evidence discussion in Section 3 of USEPA (2024a) and USEPA (2024b)). The EPA disagrees with the commenter who claimed that the EPA ignored results from animal toxicological studies. Not only did the EPA rely on animal toxicological studies to determine the overall evidence integration summary judgments, but the EPA also selected animal toxicological studies to serve as the basis of candidate RfDs and CSFs (USEPA, 2024d; USEPA, 2024c). Consistent with methodologies in the IRIS Handbook, the EPA preferentially relied on epidemiological studies to limit the variability that is associated with extrapolation from animal to human exposure (USEPA, 2022a). However, the animal toxicological literature database was critical to the EPA's hazard

conclusions in the final toxicity assessment. See also sections 4.1.1 and 4.1.2 of this *Response to Comments* document.

A few comments, including one co-signed by many commenters, expressed support for the reference doses derived by the EPA. Specifically, commenters supported the use of epidemiological data to derive the RfDs for PFOA and PFOS, the selected uncertainty factors, and the selected critical effects. A few commenters provided specific arguments against the individual health effects prioritized by the EPA. Specifically, a few commenters stated that the agency improperly relied on changes in epidemiological biomarkers (i.e., antibody response, alanine aminotransferase (ALT), and total cholesterol (TC)) or effects (i.e., (LBW) which the commenters claimed are not clinically adverse and may be reversible, rather than disease outcomes, to serve as the basis for candidate RfDs. On the other hand, one comment representing thirty-six commenters provided supportive discussion on the biological significance of endpoints including ALT and antibody response to vaccination. A few commenters questioned whether studies reporting on effects observed in populations outside the U.S. with varying exposure histories (e.g., the Faroe Islands population) are relevant to the U.S. general population.

The EPA and the SAB PFAS Review Panel agree that the four selected critical effects (i.e., decreased antibody response to vaccination, increased serum ALT, increased TC, and decreased birthweight) are biologically significant effects and/or precursors to disease (e.g., CVD), which, according to agency guidance and methods, both warrant consideration as the basis of RfDs for PFOA and PFOS (USEPA, 2002; USEPA, 2005; USEPA, 2022b; USEPA, 2022a). The EPA describes rationale for these decisions in Section 4.1 of the toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c). Briefly, effects such as increased TC, increased ALT, decreased antibody response to vaccination, and decreased birthweight resulting from PFOS or PFOA exposure may or may not result in changes that would be considered clinically elevated in a particular individual. However, given the distribution of individual concentrations within the population, small changes in the average response of these endpoints can result in substantial health impacts at the population level (Gilbert and Weiss, 2006). The SAB PFAS Review Panel shared these sentiments and noted, "one or more studies, for each of the four [noncancer health] effects, reported an association of PFOA and/or PFOS with increased risk of a clinically abnormal value… In studies where the number of subjects with clinically abnormal values was not specifically evaluated, an increase in the number of subjects with a clinically abnormal value is also expected from the overall change (shift in the distribution curve) in the abnormal direction. While the clinical relevance of exposure to PFOA or PFAS cannot be predicted on an individual basis, the increased number of individuals within a population with clinically defined abnormal values is of public health concern" (USEPA, 2022b).

Unless data suggests otherwise, the EPA considers studies published outside of the U.S. as relevant to the U.S. population; the EPA's currently established methods and protocols do not outline restrictions based on study or data source location, as this factor does not necessarily influence the confidence in study conclusions (USEPA, 2022a; USEPA, 2021a). Further, none of the commenters provided any data to support that populations outside of the U.S. would respond

to PFOA or PFOS exposure differently than the U.S. general population or vulnerable populations. Additionally, whenever possible, the EPA considered results reported in populations from multiple geographic regions and varying exposure histories when synthesizing and integrating the available evidence and when selecting critical studies for dose-response modeling. For example, at the time of the proposed rule, data originating from the U.S. were limited for the antibody response endpoint. The EPA therefore considered studies in children from the Faroe Islands (Budtz-Jørgensen and Grandjean, 2018), Greenland (Timmermann et al., 2021), Norway (Granum et al., 2013), and Germany (Abrahams et al., 2020). The observation of consistent responses across varying populations is a strength of the database, not a weakness, as some commenters erroneously imply. Since publication of the draft toxicity assessments, a study reporting anti-rubella immunity in U.S. children has also been published, further supporting and strengthening the potential relevance and weight of evidence of antibody response as an endpoint for the U.S. population (Zhang et al., 2023).

A couple commenters expressed support for the CSFs derived by the EPA. Specifically, commenters supported the use of epidemiological data to derive the CSF for PFOA and/or the use of liver tumor data to derive the CSF for PFOS. A few commenters stated that the EPA should not have relied on Shearer et al. (2021) as the basis of the CSF for PFOA because they assert that it is low confidence (in contrast to the EPA's conclusion that it is a *medium* confidence study), reports only a single PFOA serum measurement, and is not supported by the other epidemiological studies of kidney cancer, among other concerns they expressed. A couple commenters criticize the CSF for PFOS because it relies on animal evidence (i.e., liver tumors) that they claim may not be relevant to humans.

The EPA determined that Shearer et al. (2021) is a *medium* confidence study after conducting study quality evaluation consistent with the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a). The details of the study evaluation are publicly available (https://hawc.epa.gov/summary/visual/assessment/100500248/PFOA-Human-Study-Quality-Evaluations-Cancer/). The biomonitoring measures of PFOA levels in Shearer et al. (2021) were reliable measures of PFOA exposure due to the chemical's well-established long half-life in humans (see Section 3.5.1 of the Final Human Health Toxicity Assessment for PFOA (USEPA, 2024a)). Additionally, an adequate study of cancer outcomes requires consideration of the latency period of the disease (USEPA, 2005). Since cancer is not an acute outcome that develops immediately following chemical exposures, a measurement of serum PFOA one decade prior to diagnosis was appropriate. One commenter cited one *medium* and one *low* confidence studies that did not report statistically significant associations between PFOA and kidney cancer to support their claim of inconsistency in the database. The EPA disagrees with the commenter's characterization of the database because, unlike the EPA's discussion in the draft and final toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c), the commenter failed to acknowledge the entire body of evidence which includes another *medium* confidence study that reports increases in kidney cancer with PFOA exposure (Vieira et al., 2013) and a meta-analysis that also reports a positive association (Bartell et al., 2021). Additionally, Steenland et al. (2020) discusses the probable link between kidney

cancer and PFOA exposure. Importantly and in accordance with the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a) and EPA's 2005 *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005), the EPA considers the full weight of evidence approach when characterizing hazard.

As described previously in this notice and in the toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c), and as supported by other commenters, the EPA maintains that the tumors observed in rats administered PFOA or PFOS may be relevant to humans. The EPA's rationale underlying mechanistic considerations of these tumor types is described further in responses to comments below and in section 4.1.4 of this *Response to Comments* document. Additionally, evidence from recently published epidemiological studies shows concordant associations between PFOS serum concentrations and HCCs in humans (Goodrich et al., 2022; Cao et al., 2022).

Individual Public Comments and EPA Responses

4.2.2.1 Derivation of the Noncancer Reference Doses (RfDs)

New York State Department of Health (NYS DOH) (Doc. #1677, SBC-044961)

Proposed Reference Doses and Cancer Potency Factors: The proposed rule identifies reference doses (RfDs) and cancer potency factors for both PFOA and PFOS. If the rule is adopted, it is critical for EPA to clarify the status of these toxicity values. Is the Agency planning to include the PFOA and PFOS RfDs and cancer potency factors on the Integrated Risk Information System, or use them as the basis for guidelines for various environmental media for other EPA programs? For example, the Regional Screening Levels for Chemical Contaminants at Superfund Sites [FN11: https://www.epa.gov/risk/regional-screening-levels-rsls-generic-tables] currently use the minimal risk levels (MRLs) for PFOA and PFOS (3 and 2 ng/kg/day, respectively) derived by the Agency for Toxic Substances and Disease Registry (ATSDR, 2021). These MRLs lead to residential tap water guidance values of 40 ng/L and 60 ng/L for PFOA and PFOS, respectively, which greatly exceed the proposed MCLs (4 ng/L). Adoption of the reference doses (0.03 and 0.1 ng/kg/day for PFOA and PFOS, respectively) and cancer potency factors (0.0293 and 3.95x10-5 per ng/kg/day for PFOA and PFOS, respectively) in the proposed rule will likely result in Regional Screening Levels at Superfund Sites being below the analytical levels of detection. It is critical for the Agency to describe how the underlying toxicological science will be applied consistently across programs.

EPA Response: The commenter requested clarification on the status of the draft toxicity values published at the time of rule proposal. These values are considered final upon publication of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c). These values were not developed by the Office of Research and Development's IRIS and will therefore not be available on the IRIS website. The toxicity assessments and other materials supporting the rulemaking can be found in the docket EPA-HQ-OW-2022-0114. With the publication of the final toxicity assessments with this final rulemaking, other agency programs may choose to rely

on the final toxicity values for PFOA and PFOS published therein (USEPA, 2024d; USEPA, 2024c). Further discussion on the adoption of the final toxicity values for PFOA and PFOS across other agency programs is outside the scope of this rulemaking.

Consumer Reports (Doc. #1656, SBC-043187, SBC-043188 & SBC-043189)

The EPA considers noncancer effects when setting MCLGs. EPA can use the Reference dose (RfD), defined as the maximum acceptable oral dose of a toxic substance below which no adverse noncancer health effects should result from a lifetime of exposure. For PFOA, EPA followed the recommendations of the Science Advisory Board (SAB) to focus its review "on those health outcomes that have been concluded to have the strongest evidence, including liver disease, immune system dysfunction, serum lipid aberration, impaired fetal growth, and cancer." EPA identified four prioritized health outcomes from all the toxicity data on PFOA: immune (decreased antibody production in response to vaccinations), developmental (low birth weight), cardiovascular (increased serum total cholesterol), and hepatic (elevated ALT). The RfDs for the immune, developmental and cardiovascular effects were the same, i.e., 3 x 10-8 mg/kg/day, and are protective of effects that may occur in sensitive populations (i.e., infants and children). Thus, EPA set the overall RfD at 3 x 10-8 mg/kg/day for PFOA.

For PFOS, it turned out that EPA identified the same four prioritized health outcomes as for PFOA: immune (decreased antibody production in response to vaccinations), developmental (low birth weight), cardiovascular (increased serum total cholesterol), and hepatic (elevated ALT). The RfDs for the developmental and cardiovascular effects were the same, i.e., 1 x 10-7 mg/kg/day. Thus, EPA set the overall RfD at 1 x 10-7 mg/kg/day for PFOS.

We support EPA's proposed RfDs for PFOA of 3 x 10-8 mg/kg/day and for PFOS of 1 x 10-7 mg/kg/day.

EPA Response: The comments provided by this commenter support the final rule.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053371)

2. EPA takes an inappropriate approach to average/weigh all endpoints equally

For PFOA, EPA relies on the immune, developmental, and cardiovascular outcomes as co-critical effects. For PFOS, EPA relies on developmental and cardiovascular outcomes as the co-critical effects. EPA chooses these values because they are the lowest of the values presented, and EPA finds that they will be protective of other effects and protective of effects that may occur in sensitive populations [FN122: 88 Fed. Reg. 18659 and 18663.]. EPA provides no scientific weight of evidence analysis and simply chooses the lowest numbers. If SDWA were a precautionary statute, then it would not direct EPA to use the best available public health information and data collected by the best methods. In this case, EPA ignores the statutory standard and picks the lowest numbers. SDWA also requires EPA to specify uncertainties, identify studies that would assist in resolving the uncertainties, and also reconcile inconsistencies

in the scientific data [FN123: 42 U.S.C. [sec] 300g-1(b)(3)(B)(iv).]. While EPA discusses uncertainties in the benefit and costs analysis, the proposed rule does not provide any substantive discussion of the uncertainties associated with the derivation of the RfD values. Finally, while the proposed rule notes inconsistencies in some of the data sets, as described for some of the endpoints in comments above, EPA makes no effort to resolve these inconsistencies.

EPA Response: The commenter disagreed with the EPA's approach to select co-critical effects to serve as the basis for the RfDs for PFOA and PFOS. The commenter stated that the EPA chose those values because they are the lowest presented and will be protective of effects in sensitive populations. The commenter stated the EPA did not provide a weight of evidence analysis and ignored the SDWA requirement to use the best available science. The commenter stated SDWA "requires EPA to specify uncertainties, identify studies that would assist in resolving the uncertainties, and also reconcile inconsistencies in the scientific data" and the EPA did not "provide any substantive discussion of the uncertainties associated with the derivation of the RfD values." The commenter lastly states that the EPA made no effort to resolve inconsistencies in the database. The EPA disagrees with these comments.

Regarding the selection of co-critical effects, the agency did not "average" the values across candidate RfDs; the candidate RfDs for immune, developmental, and cardiovascular (PFOA) and developmental and cardiovascular (PFOS) were the same when rounded to one significant figure. The EPA determined that it was appropriate to select co-critical effects to serve as the basis of the overall RfDs for PFOA and PFOS as a result of the weight of evidence analyses (i.e., evidence integration) presented in Section 3 for each health outcome (USEPA, 2024d; USEPA, 2024c), that the commenter incorrectly stated the EPA did not conduct. When considering data from epidemiological, animal toxicological, and mechanistic evidence streams, the EPA judged the immune, hepatic, developmental, and cardiovascular health outcomes to each have *evidence indicating* that PFOA or PFOS exposure is likely to cause adverse effects in humans under relevant exposure circumstances (see evidence integration protocols in Appendix A (USEPA, 2024a; USEPA, 2024b) and USEPA, 2022a). As such and considering the strengths of the modeled data for each health outcome and endpoint, described in Appendix E (USEPA, 2024a; 2024b), the EPA did not have evidence to distinguish one health outcome or endpoint over the other(s) when selecting an overall RfD. Therefore, the EPA selected co-critical effects to serve as the basis for the overall RfDs. This decision is in line with previous agency decisions to derive RfDs based on co-critical effects from varying health outcomes (e.g., IRIS PFBA assessment (USEPA, 2022c), 1,4-dioxane assessment (USEPA, 2013)). For further discussion on the EPA's use of the best available science, please see section 4.1.2 of the EPA response in this *Response to Comments* document.

Additionally, for PFOA, the overall RfD selected (3×10^{-8} mg/kg/day) was not the lowest possible candidate RfD derived (2×10^{-8} mg/kg/day, based on Timmerman et al., 2021). Similarly, for PFOS, the lowest possible candidate RfD for immune effects (1×10^{-7} mg/kg/day, based on Timmerman et al., 2021) was not selected as the immune health outcome-specific RfD (2×10^{-7} mg/kg/day, based on Budtz-Jorgensen & Grandjean, 2018). For these instances and

others where the EPA did not select the most health protective (i.e., lowest) possible candidate RfD, the EPA provided rationale in Section 4 and Appendix E (when the decision was related to POD derivation) of the draft and final toxicity assessments (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). Regardless, as the commenter stated, the EPA's overall RfDs are expected to be protective of effects that may occur in sensitive populations.

The EPA lastly disagrees with the commenter's assertions that the agency did not discuss uncertainties in the RfDs or inconsistencies in the database. Both of these factors are discussed throughout the toxicity assessments in the context of evidence synthesis and integration (Section 3), critical study and endpoint selection (Sections 3 and 4), PK and BMD modeling approaches (Section 4 and 5), and candidate RfD selection (Section 4), among other topics (USEPA, 2024d; 2024b). As described in Appendix A (USEPA, 2024a; USEPA, 2024b) and USEPA (2022a), inconsistencies in the database play a critical role in the EPA's evidence integration judgment, as well as selection of critical effects. For example, in the PFOS toxicity assessment, the EPA stated: "Although a few associations between other liver serum biomarkers [besides ALT] and PFOS exposure were identified in *medium* confidence epidemiological studies, there is considerable uncertainty in the results due to inconsistency across studies" (USEPA, 2023a). As such, the EPA did not consider liver serum biomarkers other than ALT for BMD modeling or candidate RfD derivation. Similar statements can be found throughout Section 3 of the PFOA and PFOS toxicity assessments for other endpoints and health outcomes (USEPA, 2024d; 2024b). Notably, the EPA identified generally consistent associations in *medium* and *high* confidence studies between PFOA or PFOS and the endpoints of decreased antibody response in children, decreased birthweight, increased serum ALT in adults, and increased serum TC in adults, as well as coherent and supportive evidence for these endpoints in animal toxicological studies. These findings facilitated the EPA's selection of these endpoints and associated studies for BMD modeling.

The EPA provided extensive discussion of several uncertainties related to the development of these assessments in Section 6 of the draft toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a). Specifically, the EPA discussed: uncertainties in the use of epidemiological studies for quantitative analyses; quantitative differences and uncertainties underlying comparisons between RfDs derived from animal toxicological and epidemiological studies; inconsistencies between approaches used in development of the 2016 HESDs (USEPA, 2016b; USEPA, 2016a) and the 2023 draft assessments (USEPA, 2023f; USEPA, 2023a); uncertainties in the cancer classification determination; uncertainties related to health outcomes with evidence bordering on "indicating" associations; uncertainties in modeling (i.e., animal internal dosimetry, human dosimetry, and BMD modeling); and uncertainties regarding sensitive subpopulations.

WV Municipal Water Quality Association (Doc. #1816, SBC-044664)

We question whether EPA has appropriately used the public health PFAS-related data available to it in lieu of extrapolating from literature values and animal studies.

We question whether EPA has adequately used the public health tracking data available to it from the various health tracking initiatives of individuals exposed to elevated PFAS levels from around the country.

To begin with, EPA has literally decades of actual human health PFOA-PFOS data available to it courtesy of the Food and Drug Administration. We understand that FDA has over twenty years of actual blood PFAS level sampling data for thousands of Americans as depicted in the chart below.

Rather than extrapolating from this wealth of human data, it appears that EPA chose to extrapolate from literature values and animal studies. Doing so resulted in EPA injecting an enormous margin of uncertainty multiplier into the criteria that we don't believe is warranted or justified.

[Figure 1: see docket ID EPA-HQ-OQ-2022-0114-1820]

For example, beyond FDA's data, EPA has available to it years of health monitoring data for impacted residents in Parkersburg/Vienna, West Virginia as well as other systems around the country such as Wilmington, North Carolina. States closely track public health clusters and yet we are not aware of any in these communities associated with elevated PFAS levels.

EPA must address this critical health data, along with its partners such as the West Virginia Department of Environmental Protection and Bureau of Public Health (regarding the Parkersburg/Vienna data) as well as the North Carolina Department of Environmental Quality (as to PFAS-related heath data for Cape Fear River communities).

More generally, EPA's 2023 proposed MCLs are based on a lifetime consumption of 2.5 liters per day for 70 years. In addition, the MCLs are based on rat/mice studies with a 300x uncertainty factor, comprising 10x for intraspecies variability, 3x for interspecies differences and 10x for database deficiencies. Note, that the study found no evidence to support lower birthrate at human serum levels included in the data sets.

[Figure 2: see docket ID EPA-HQ-OQ1820]

https://www.whitehouse.gov/wp-content/uploads/2023/03/OSTP-March-2023-PFAS-Report.pdf

[Figure 3: see docket ID EPA-HQ-OQ-2022-0114-1820]

[Figure 4: see docket ID EPA-HQ-OQ-2022-0114-1820]

Literature suggests that rats/mice are poor models for certain chemical health interactions in humans. The uncertainty factor is large and the basis for lifetime consumption wasn't validated. Given the prevalence of epidemiological studies and the breadth of available health information regarding PFOA and PFOS, it was error by EPA not to use human data to guide the proposed MCL regulation and EPA's failure is inconsistent with the approach taken by major health authorities in other developed nations.

EPA Response: The commenters appear to misunderstand several aspects of the science underlying the PFAS NPDWR, particularly the MCLGs for PFOA and PFOS. Please see sections 4.1.4 and 4.2.2 of the EPA response in this *Response to Comments* document. In contrast to the commenter's assertion, the EPA did use human data published in peer-reviewed epidemiological studies to develop toxicity values (i.e., RfDs and CSFs), when available. Data from human studies were significant to the EPA's determination that PFOA and PFOS are *Likely to be Carcinogenic to Humans* and subsequent determinations that the MCLGs for PFOA and PFOS should be set to zero. Further, the candidate RfDs derived from epidemiological studies incorporated a composite uncertainty factor of 10x, which is not "an enormous margin of uncertainty multiplier…" as the commenter suggests. Several epidemiological studies the EPA selected for candidate RfD derivation relied on data from NHANES, one source of "public health tracking data available" from the general U.S. population (e.g., Dong et al., 2019) and others relied on "individuals exposed to elevated PFAS levels" from impacted communities, such as the C8 Health Project subjects (e.g., Gallo et al., 2012).

The EPA considered all publicly available, peer-reviewed data, as well as data collected by accepted or the best available methods in the agency's assessments of PFOA and PFOS, including published studies of "public health clusters," in order to identify potential associations between these two chemicals and adverse health effects that may be observed in the U.S. population. The EPA is unaware of biomonitoring efforts undertaken by FDA that report PFOA and PFOS concentrations in human biological samples and the commenter did not provide a citation for their assertion. However, the EPA did incorporate monitoring of environmental media (e.g., food) conducted by FDA in its derivation of the relative source contribution (RSC), presented in Appendix G of the draft and final toxicity assessments (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b).

The commenter also mistakenly stated that the "EPA's 2023 proposed MCLs are based on a lifetime consumption of 2.5 liters per day for 70 years." The EPA assumes the commenter is referring to the additional PFAS (i.e., HFPO-DA, PFBS, PFNA, and PFHxS) for this statement, as the MCLGs PFOA and PFOS were zero and did not incorporate assumptions regarding drinking water ingestion (see section 4.1.5 of the EPA response in this *Response to Comments* document). Regardless, the EPA described in the *Maximum Contaminant Level Goals (MCLGs) for Three Individual Per- and Polyfluoroalkyl Substances (PFAS) and a Mixture of Four PFAS.* (USEPA, 2024h) that drinking water consumption values were based on data presented in the 2019 edition of the *Exposure Factor's Handbook* (USEPA, 2019) and are specified for the target population presented in the critical study of interest. This does not equate to lifetime consumption of 2.5 L/day for 70 years in calculations of the HBWCs or MCLGs for any of the four additional PFAS considered in this rulemaking. The commenter also mistakenly asserts that all of the RfDs were derived with a composite uncertainty factor of 300x. As described above, the composite UF used in the overall RfDs for PFOA and PFOS was 10x (10x for intraspecies variability), while the composite uncertainty factor used in the RfD for HFPO-DA was 3,000x (10x for intraspecies variability, 3x for interspecies differences, 10x for extrapolation from a subchronic to a chronic dosing duration, and 10x for database deficiencies). These are reasonable

and standard uncertainty factors, applied based on the specific information available for each PFAS contaminant, consistent with long-standing EPA guidance and methods (USEPA, 2002; USEPA, 2022a).

The EPA disagrees that "literature suggests that rats/mice are poor models for certain chemical health interactions in humans" and the commenter does not provide citations to support this claim. While the EPA agrees that there are uncertainties associated with the extrapolation of data from animal models to humans (see discussion in section 4.2.2 of this *Response to Comments* document), the EPA disagrees that this precludes the agency from quantitatively relying on studies in animal models for the derivation of toxicity values. This practice has been used to support agency products for decades and is repeatedly endorsed by EPA guidance and methods (USEPA, 2002; USEPA, 2005; USEPA, 2014a; USEPA, 2022a). The EPA agrees that extrapolation from animal models to humans is complex, but animal toxicological studies, regardless of study design characteristics such as dose levels, are critical for determining potential human health hazards and the exposure levels and internal doses (e.g., serum concentrations) that may be expected to cause adverse health effects in humans. With an understanding of how the chemical exposure behaves differently in animals and humans, the EPA can estimate the equivalent level of exposure that would pose a risk to human health and compare those values across any effects that could pose a hazard. In this way, the EPA can determine the minimum exposure level (e.g., RfD) that could result in a risk to human health.

Association of MO Cleanwater Agencies (Doc. #1817, SBC-044642)

We question whether EPA has appropriately used the public health PFAS-related data available to it in lieu of extrapolating from literature values and animal studies.

We question whether EPA has adequately used the public health tracking data available to it from the various health tracking initiatives of individuals exposed to elevated PFAS levels from around the country.

To begin with, EPA has literally decades of actual human health PFOA-PFOS data available to it courtesy of the Food and Drug Administration. We understand that FDA has over twenty years of actual blood PFAS level sampling data for thousands of Americans as depicted in the chart below.

Rather than extrapolating from this wealth of human data, it appears that EPA chose to extrapolate from literature values and animal studies. Doing so resulted in EPA injecting an enormous margin of uncertainty multiplier into the criteria that we don't believe is warranted or justified.

[Figure 1: see docket ID EPA-HQ-OQ-2022-0114-1820]

For example, beyond FDA's data, EPA has available to it years of health monitoring data for impacted residents in Parkersburg/Vienna, West Virginia as well as other systems around the

country such as Wilmington, North Carolina. States closely track public health clusters and yet we are not aware of any in these communities associated with elevated PFAS levels.

EPA must address this critical health data, along with its partners such as the West Virginia Department of Environmental Protection and Bureau of Public Health (regarding the Parkersburg/Vienna data) as well as the North Carolina Department of Environmental Quality (as to PFAS-related heath data for Cape Fear River communities).

More generally, EPA's 2023 proposed MCLs are based on a lifetime consumption of 2.5 liters per day for 70 years. In addition, the MCLs are based on rat/mice studies with a 300x uncertainty factor, comprising 10x for intraspecies variability, 3x for interspecies differences and 10x for database deficiencies. Note, that the study found no evidence to support lower birthrate at human serum levels included in the data sets.

[Figure 2: see docket ID EPA-HQ-OQ1820]

https://www.whitehouse.gov/wp-content/uploads/2023/03/OSTP-March-2023-PFAS-Report.pdf

[Figure 3: see docket ID EPA-HQ-OQ-2022-0114-1820]

[Figure 4: see docket ID EPA-HQ-OQ-2022-0114-1820]

Literature suggests that rats/mice are poor models for certain chemical health interactions in humans. The uncertainty factor is large and the basis for lifetime consumption wasn't validated. Given the prevalence of epidemiological studies and the breadth of available health information regarding PFOA and PFOS, it was error by EPA not to use human data to guide the proposed MCL regulation and EPA's failure is inconsistent with the approach taken by major health authorities in other developed nations.

EPA Response: Please see the EPA response to comment Doc. #1816, SBC-044664 in section 4.2.2.1 in this *Response to Comments* document.

NC Water Quality Association (Doc. #1818, SBC-044620)

We question whether EPA has appropriately used the public health PFAS-related data available to it in lieu of extrapolating from literature values and animal studies.

American Chemistry Council (ACC) (Doc. #1841, SBC-044825)

EPA's Assessment of the Human Health Effects is Flawed

EPA's proposed drinking water standards for the six PFAS relies on a selective analysis of the available health effects information that does not consider the entire full weight of available scientific evidence. This failure to consider all of the available evidence can be seen in the cancer slope factor (CSF) and multiple reference doses (RfDs) developed for PFOA and PFOS.

EPA Response: Please see section 4.2.2 of the EPA response in this *Response to Comments* document.

4.2.2.2 The EPA's Reliance on Epidemiological Data to Support RfD Derivation

4.2.2.2.1 Critical Study Selection

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-045903)

B. Epidemiology data do not support an association for PFOA/PFOS immune, developmental, cholesterol, and hepatic (liver) endpoints

EPA has chosen to rely on epidemiology data for four critical endpoints for the development of the RfDs for the non-cancer effects of PFOA and PFOS and has inappropriately ignored high-quality animal data. An important comment made by the SAB was related to EPA's lack of transparent process for evidence synthesis and integration. SAB also directed EPA to consider multiple animal and human studies for a variety of endpoints [FN103: See SAB report to the EPA Administrator Aug. 22, 2022, in the cover letter to Administrator Regan, available at: https://sab.epa.gov/ords/sab/f?p=100:18:16490947993:::RP,18:P18_ID:2601#report.]. Yet, for quantitative derivation of the RfD values, EPA did not follow SDWA requirement to use "best available public health information," and instead relied on non-binding EPA guidance and used human data for all endpoints, even when higher confidence animal data existed [FN104: 88 Fed. Reg. 18661 (EPA states: "The focus of this FRN is on epidemiological studies for the four

prioritized health outcomes for which studies meeting this consideration were available, as human data are generally preferred 'when both laboratory animal data and human data with sufficient information to perform exposure-response modeling are available' (USEPA, 2022f).")]. This non-binding guidance sets a bar at "sufficient information," which is not consistent with SDWA requirement for "best available public health information."

EPA must develop a consistent, transparent, and peer-reviewed approach for deriving and choosing candidate RfD values which is based on SDWA requirements. This means that candidate RfD values should be developed based on concordance of both animal and human data, and EPA should take comment on them and rely on the highest quality evidence, with a robust and transparent scientific rationale [FN105: As discussed previously, SAB review is also required by the SDWA. EPA's new framework for evaluating evidence and the resulting values from animal and epidemiological data should be reviewed by the SAB.]. Instead, EPA relied on medium quality studies for three of the four endpoints and does not even present results from animal evidence in the Federal Register notice for the proposed rule. This choice made a material difference in the MCL levels. For instance, for hepatic effects of PFOS, if EPA had relied on the high quality animal data, rather than the medium quality human data, the resulting RfD would have been three orders of magnitude higher [FN106: See Public Comment Draft Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) in in Drinking Water (Public Comment Draft Assessments), at page 4-44, available at: https://www.regulations.gov/document/EPA-HQ-OW-2022-0114-0034.]. The approach provided in the proposed rule is not scientifically robust and not consistent with SDWA standards for scientific information.

EPA Response: Regarding the EPA's use of epidemiological data to serve as the basis of the overall RfDs and the commenter's claim that the EPA "ignored" animal toxicological data, please see section 4.2.2 of the EPA response in this *Response to Comments* document. Regarding the EPA's use of the "best available science," see section 4.1.2 of the EPA response in this *Response to Comments* document. Regarding how the EPA responded to SAB comments, see section 4.1.3 of the EPA response in this *Response to Comments* document and the Response to SAB Comments document (USEPA, 2023d). Regarding comparisons between RfDs derived from animal toxicological studies and epidemiological studies, please see the discussion that was provided at the time of rule proposal in Section 6.2 of the draft toxicity assessments (USEPA, 2023f; USEPA, 2023a; now Section 5.2 of the final assessments, USEPA, 2024d; USEPA, 2024c). Regarding the systematic review protocol used for this assessment, see section 4.1.1 of the EPA response in this *Response to Comments* document.

Additionally, there is no requirement, nor is it reasonable or practical for the expectation of one, that the agency "rely on the highest quality evidence," particularly considering how different study evaluation domains are across animal toxicological and epidemiological studies (see Appendix A (USEPA, 2024a; USEPA, 2024b) and USEPA (2022a)). Because different factors are considered with evaluating epidemiological and animal toxicological studies, it is difficult to make direct comparisons about study confidence ratings across the two evidence streams. The

EPA also must consider quantitative uncertainties with the extrapolation of data from animal studies to inform human health toxicity values. Finally, study selection guidance (Section 7.2) from the IRIS Handbook notes that "human are preferred over animal data to eliminate interspecies extrapolation uncertainties," and that animal studies "are considered the studies of primary interest when adequate human studies are not available" (USEPA, 2022a). The uncertainties associated with the use of animal toxicological studies and rationale for the selection of epidemiological studies to serve as the basis of the health outcome-specific and overall RfDs for PFOA and PFOS is described in Section 4.1.6 of the toxicity assessments (USEPA, 2024c; USEPA, 2024a).

3M Company (Doc. #1774, SBC-053431)

EPA was subjective and inconsistent in selecting key studies for BMD derivation.

In contrast to the systematic review practices recommended in EPA's IRIS Handbook, as well as best practice in risk assessment, EPA does not clearly describe the process for selection of key studies for use in BMD and BMDL derivation (see Section 2 for comments regarding study selection). Many studies judged as high- and medium-quality on CVD outcomes were not considered for POD derivation, including serum lipids, birth weight, and vaccine responses. EPA (2012) Benchmark Dose Technical Guidance states that, "The process of selecting studies for BMD analysis is intended to identify those studies for which modeling is feasible, so that BMDs can be calculated. All relevant studies should be considered for modeling…Sometimes combining several datasets may be an option [emphasis added]" (EPA 2012, p.14). However, EPA does not discuss why it did or did not consider specific studies, and thus the selection of the studies for BMD modeling appears to be subjective.

There are several examples in which EPA judged a study as medium- or low-confidence and contained data but did not model (or describe justification for not modeling) the available coefficients or dose-response information. For example, Mogensen et al. (2015) published an analysis on vaccine response at age seven within the Faroe Islands cohort; this analysis accounts for confounding and co-exposures to additional PFAS in the population through use of a Structural Equation Model (SEM). Mogensen et al. (2015) report that "When the three latent PFASs were mutually adjusted the associations became less apparent and only anti-tetanus antibody showed a borderline significant decrease by 29.6% (95% CI: -0.4%, 50.6%) at a doubling of PFOA exposure after this adjustment." Mogensen et al. (2015) also stated that their analyses "indicated that the causative dose is a long-term average where all three PFASs may contribute. Such an analysis would not be meaningful in standard regression models, as it would require that all exposure variables were included simultaneously as independent variables". Budtz-Jørgensen, in a 2007 article on the use of SEMs for estimation of benchmark doses, argues that dose-response modeling based on the assumed most sensitive outcomes "ignores other available data, is inefficient, and fails to account for multiple testing. Instead, risk assessment could be based on [SEMs], which can accommodate both a multivariate exposure and a multivariate response function" (Budtz-Jørgensen 2007). Budtz-Jørgensen (2007) argues "an

unbiased analysis can only be obtained in models that allow for measurement error" and proposes the use of SEMs for BMD analysis to account for and mitigate potential biases from measurement error. It is not clear why, based on the available evidence, EPA chose not to consider the findings from Mogensen et al. (2015) in addition to those from BudtzJørgensen and Grandjean (2018a) and Timmerman et al. (2021).

Lack of transparency in key study selection is not limited to the analyses of immune effects, however. EPA does not clearly describe its process for choosing the cross-sectional analyses by Dong et al. (2019), Steenland et al. (2009) and Lin et al. (2019) as the most appropriate studies for derivation of BMD(L)s for changes in serum lipids, nor does EPA provide justification of its selection of Chu et al. (2020), Govarts et al. (2016), Sagiv et al. (2018), Starling et al. (2017), Wikstrom et al. (2020), or Yao et al. (2021) for deriving BMD(L)s based on decreases in birth weight (see Section 2).

EPA Response: The commenter stated the EPA did not fully and transparently describe key study selection for POD derivation and that the process appeared to be subjective. The commenter provided one example, Mogensen et al. (2015), which reported an inverse association between PFOA and serum anti-tetanus antibodies in the Faroe Islands population. The commenter noted that Mogensen et al. (2015) used Structural Equation Modelling (SEM) analyses and cited a paper by Budtz-Jorgensen (2007) as supportive evidence. The commenter claimed that the EPA was not transparent in study selection for POD derivation across the serum lipid and LBW effects as well.

The EPA disagrees with the claim that critical study selection was not transparently described. In the health effects evidence synthesis and integration sections (sections 3.4 and 3.5 of the draft toxicity assessments for noncancer and cancer effects, respectively (USEPA, 2023f; USEPA, 2023a)), the EPA presented evidence integration judgments for each health outcome. The EPA used these judgments to determine which health outcomes and endpoints should be considered for quantitative analyses (i.e., only health outcomes with databases meeting criteria for evidence demonstrates or evidence indicates integration judgments were considered for dose-response assessment). In the dose-response assessment section of the documents (Section 4 of the draft assessments (USEPA, 2023f; USEPA, 2023a)), the EPA presented a description of each endpoint selected for quantitative analysis and the reasons for selection, the strength of the database in support of each endpoint, consistency of findings in the database, and the relevance of each endpoint to human health. The EPA lists the studies considered for POD derivation and provides confidence ratings for each study discussed. The EPA provides reasons for candidate study selection related to study design and analysis approach (Section 4.1.1, USEPA, 2024d; USEPA, 2024c) and follows the protocol outlined in the Appendix (Section A.1.11.1, USEPA, 2024a; USEPA, 2024b). The selected candidate studies were the best suited for POD derivation for multiple reasons, such as consideration of potential confounding factors, overall study confidence, study design and analysis, and suitability for modeling, among others described in the assessments. In response to public comments, the EPA has continued to improve the transparency and discussion related to candidate study selection, modeling, and RfD derivation

across each of the five priority health outcomes and critical effects, including increased total cholesterol, decreased BWT, increased ALT, and decreased antibody response to vaccination.

The EPA also disagrees with the commenter that the findings from Mogensen et al (2015) were not considered. As detailed in section 3.4.2.1.1.1 and Table 3-6 of the draft toxicity assessment for PFOA (USEPA, 2023f), the EPA clearly considered the findings from all the Faroe Island studies identified in the systematic literature review. The commenter asserted that the EPA should have considered using the estimates from structural equation modelling (SEM) provided in Mogensen et al. (2015) to "account for potential biases resulting from measurement error." The EPA agrees that SEM has the advantage of, if specified correctly, accounting for measurement error. However, both regression models (used in Budtz- Jørgensen and Grandjean (2018)) and SEMs ultimately estimate adjusted effects of one specific pollutant, while accounting for the others.

Mogensen et al. (2015) provides cross-sectional estimates of change in antibody levels at age 7 associated with changes in PFOS at age 7, with and without adjustment of PFOA and PFHxS. While this approach accounts for measurement error, it is more complex and it requires additional assumptions (e.g., assuming underlying latent variables) when modelling. Therefore, the modelling is only correct if the assumptions are met. Rather than Mogensen et al. (2015), the EPA selected the results from Budtz-Jørgensen and Grandjean (2018) Faroe Islands study for POD derivation. Budtz-Jørgensen and Grandjean (2018) is a *medium* confidence longitudinal study that relies on a standard statistical tool (regression models). Importantly, SEMs are not yet generally accepted for BMD modelling; the use of these estimates is not discussed in existing agency guidance (USEPA, 2012). Thus, the EPA determined that it is reasonable to rely on Budtz-Jørgensen and Grandjean (2018) for candidate RfD derivation over Mogensen et al. (2015).

American Chemistry Council (ACC) (Doc. #1841, SBC-052928)

Available Studies do not Provide Consistent Evidence of Low Birth Weight Among Infants Exposed to PFOA or PFOS In Utero

As noted in the draft documents, several human studies have investigated PFOA and PFOS exposure and birth outcomes, including birth weight. Most of these studies did not find an association between maternal serum levels and birth weight. [FN67: ATSDR PFAS Tox Profile, at 410.] Among the negative studies was an occupational exposure study in which female workers were exposed to high levels of PFOS. [FN68: Grice et al. 2007.] In many of those studies reporting an inverse relationship, moreover, the effect was small and limited to a single sex or exposure group.

Among the five studies for which EPA conducts benchmark dose modeling for developmental effects, two did not report a significant association with maternal serum concentrations of PFOA or PFOS – Govarts et al. 2016 [FN69: Govarts E et al. Combined effects of prenatal exposures to environmental chemicals on birth weight. Int J Environ Res Public Health 13:495 (2016).] and

Sagiv et al. 2017. [FN70: Sagiv SK et al. Early Pregnancy Perfluoroalkyl Substance Plasma Concentrations and Birth Outcomes in Project Viva: Confounded by Pregnancy Hemodynamics? Am J Epidemiol 187: 793-802 (2017). The association with PFOS was not significant after adjusting for potential confounders.] Moreover, Starling et al. (2017) [FN71: Starling AP et al. Perfluoroalkyl substances during pregnancy and offspring weight and adiposity at birth: Examining mediation by maternal fasting glucose in the healthy start study. Environ Health Perspect 125: 067016 (2017).] do not observe a significant association with serum concentration of PFOS and report an association only in the highest tertile of PFOA concentration. In the study by Chu et al. (2020), the association is not significant in the analysis by serum concentration quartiles for either substance or in the continuous serum concentration analysis for PFOA. [FN72: Chu C et al. Are perfluorooctane sulfonate alternatives safer? New insights from a birth cohort study. Environ Intl 135: 105365 (2020). While the OR for continuous serum concentration (per nanogram/milliliter) did not include 1, the confidence interval is quite wide (1.08, 5.47).] The final study by Wikstrom et al. (2019) [FN73: Wikström, S et al. Maternal serum levels of perfluoroalkyl substances in early pregnancy and offspring birth weight. Pediatric Res 87: 1093-1099 (2019).] report an association with PFOA and PFOS concentration in the highest quartile of girls; no association is observed in infant boys. Calculating an RfD from these epidemiology studies is inappropriate based on the higher degree of uncertainty in the findings and inconsistency across studies.

EPA Response: The commenter stated that most of the studies evaluating the association between BWT and PFOA or PFOS exposure did not find an association between maternal serum levels and BWT. The EPA disagrees with this comment. For PFOA, the majority of studies on changes in standardized BWT measures reported inverse associations (10/18), with most (7/10) of these being *high* and *medium* confidence (USEPA, 2024d). The forest plots also illustrate these associations. Similarly, the majority of studies (12/17) observed either an increased risk of LBW or small for GA. For PFOS, most evidence for deficits in mean BWT were reported from *high* or *medium* confidence studies (23/36; USEPA, 2024c). Studies on changes in standardized BWT measures reported inverse associations (12/18) in the overall population or specifically in one or both sexes. Ten of 17 studies observed increased risk of LBW or small for GA. These results are described in section 3.4.4.1 and summarized in section 3.4.4.4 of USEPA (2024a) and USEPA (2024b). Additionally, the commenter points to one occupational study, Grice et al. (2007), in which there was no association between PFOS and decreases in BWT in infants born to female workers exposed to high levels of PFOS compared to those born to females never exposed. The EPA conducted an evaluation of Grice et al., 2007 (see section 3.4.4 (USEPA, 2024c) and https://hawc.epa.gov/study/101163956/) and found this study was *deficient* for the BWT outcome. Therefore, confidence in the results from this particular study is limited. More specifically, comparing between women with "high levels" of PFOS and "never exposed" women is a crude comparison relative to studies comparing decreases in BWT per unit change in PFOS. However, the author notes that smoking was a modifying factor and "the reported birth weight for women who smoked during pregnancy compared with that for those who did not

smoke during pregnancy, adjusting for maternal age at birth and gravidity, was significant and therefore consistent with scientific knowledge (estimate -0.24 kg; 95% CI -0.12 to -0.37).

The EPA selected five (PFOA) and six (PFOS) *high* confidence studies for dose-response modeling of the decreased birthweight endpoint (USEPA, 2024d; USEPA, 2024c). The candidate epidemiological studies offer a variety of PFOA and PFOS exposure measures across the fetal and neonatal window. All studies reported their exposure metric in units of ng/mL and reported the β coefficients per ng/mL or ln(ng/mL), along with 95% CIs, estimated from linear regression models. The commenter asserted that some of the studies selected for POD derivation did not report significant associations. The EPA disagrees that using these studies is inappropriate. As stated in the EPA's *Guidelines for Developmental Toxicity Risk Assessment* (USEPA, 1991b), "Although statistical analyses are important in determining the effects of a particular agent, the biological significance of data is most relevant. It is important to be aware that with the number of endpoints that can be observed in standard protocols for developmental toxicity studies, a few statistically significant differences may occur by chance." The scientific consensus in the epidemiologic and systematic review community is that evidence of an association does not need to rely solely on statistical significance. As stated in the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a), consideration of magnitude of the association and biological significance or adversity inform determination of associations. The nature of observational studies and potential sources of bias and systematic error that can impact statistical significance also make compelling cases for not relying solely on significance to determine whether the evidence supports an association or not.

4.2.2.2.2 Adversity of the Critical Effects

Raptor Pharm & Tox, Ltd (Doc. #1644, SBC-043416)

Raptor is concerned that EPA is violating the Safe Drinking Water Act by using scientific studies that do not demonstrate an adverse human health outcome. Although these comments focus on Steenland et al. 2009, Gallo et al. 2012, and Budtz-Jorgensen and Grandjean 2018, the EPA must reconsider all of the studies used to derive the RfD and clearly articulate how each study has identified an actual adverse human health outcome, rather than simply postulating that one could or may exist.

EPA Response: Please see section 4.2.2 of the EPA response in this *Response to Comments* document. While the commenter claims they are "concerned that EPA is violating the Safe Drinking Water Act," the commenter fails to note any action the EPA took that "violates" any specific SDWA statutory requirement. Although the commenter may want the EPA to conduct analyses in a certain way, it does not mean that the agency "violated" any SDWA obligation, nor does it place any requirement on the agency.

American Chemistry Council (ACC) (Doc. #1841, SBC-052921)

For non-cancer health effects, three of the RfDs for PFOA and PFOS rely on reports of slight changes in biomarkers in epidemiology studies in the absence of information to support that these changes are predictors of disease. The decision to generate an RfD for the fourth non-cancer endpoint ignores the results of several epidemiology studies that reported no adverse effects.

EPA Response: Please see section 4.2.2 of the EPA response in this *Response to Comments* document. The EPA assumes the commenter is referring to the endpoint of decreased birthweight when describing the "fourth non-cancer endpoint." The EPA responds to claims about inconsistencies in the database for this endpoint in the EPA response to comment Doc. #1774, SBC-053211 and SBC-053428 in section 4.2.1.2 in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-052929)

EPA's PFOA and PFOS Toxicity Evaluations are not Scientifically Justified

Given all the uncertainties and limitations of the available epidemiology data, the RfDs for PFOA and PFOS should be based on robust experimental animal data that is consistent, biologically plausible and relevant in humans, and shows a dose-response relationship. MCLs should be based on RfDs for endpoints that are adverse, more than transient and irreversible, and that truly can lead to human disease. While the human data may be useful as a qualitative line of evidence, the RfDs should be based on experimental animal data with observations that provide a clear dose-response and human relevant, biologically plausible, adverse endpoints.

EPA Response: Regarding the EPA's selection of epidemiological studies rather than animal studies to serve as the basis of the overall RfDs for PFOA and PFOS, as well as discussion on the adversity of the selected critical effects, please see section 4.2.2 of the EPA response in this *Response to Comments* document. Regarding the consistency of the database for each of the four epidemiological endpoints, please see sections 4.2.1.2, 4.2.1.3, 4.2.1.4, and 4.2.1.5 of the EPA response in this *Response to Comments* document.

4.2.2.2.3 Critical Study Populations

3M Company (Doc. #1774, SBC-053287)

2. EPA does not provide evidence that the study data sets used for BMD calculation represent the US population and even when appropriate datasets are selected, they are improperly analyzed.

(2A) EPA did not verify the representational nature of datasets selected for its BMD calculation

The data underlying several key studies EPA relies as the basis for its Proposed NPDWR are unavailable for review and evaluation (see for example Budtz-Jørgensen & Grandjean, 2018). Moreover, even where data is available, EPA did not address the representativeness of the data with respect to US national level populations.

Unless individual study findings can translate directly to the US population at large, the findings cannot be used to anticipate the impact of the rulemaking on human health risk in the US. Also, without a clear and quantitative understanding of how studies based on various nonrepresentative data sets were analyzed and treated, the costs and benefits of the proposed rule cannot be assessed properly.

EPA Response: The EPA disagrees with the commenter's erroneous statement that the agency did not consider whether studies were relevant to the U.S. general population. First, please see section 4.2.2 of the EPA response in this *Response to Comments* document and the EPA Response to this commenter (Doc. #1774, SBC- SBC-053296 in section 4.2.2.2.4 in this *Response to Comments* document) below. As a further example, one factor the agency considered when selecting critical studies for candidate RfD derivation was whether the serum PFOA or PFOS concentrations reported in the population examined in each study were comparable to serum PFOA or PFOS concentrations reported in the U.S. general population (see Section 4.1 of the toxicity assessments (USEPA, 2024d; USEPA, 2024c)). However, unless there are data available indicating that a non-U.S. study population may not be relevant to the U.S. population, it would not be best practices for the agency to exclude that study from the assessment or quantitative analyses.

For discussion of the methodology utilized for the economic analysis, including the various robust, peer-reviewed approaches for estimating benefits, please see the economic analysis for this final PFAS rulemaking action and section 13 of the EPA response in this *Response to Comments* document.

New Hampshire Department of Environmental Services (NHDES) (Doc. #1690, SBC-044337 & SBC-044338)

Comments by New Hampshire Department of Environmental Services (NHDES) For the Proposed PFAS National Primary Drinking Water Regulations

Docket ID No. EPA-HQ-OW-2022-0114

Published March 29, 2023, Pages 18638-18754

May 30, 2023

1. Page 18729, Column 3, Section V – Maximum Contaminant Level Goal

a. Section V, Part A.2c. Page 18,660, Column 1, 1st Paragraph - EPA is seeking comment on the derivation of the proposed MCLG for PFOA, its determination that PFOA is Likely to be Carcinogenic to Humans and whether the proposed MCLG is set at the level at which there are no adverse effects to the health of persons and which provides an adequate margin of safety. EPA is also seeking comment on its assessment of the noncancer effects associated with exposure to PFOA and the toxicity values described in USEPA (2023b).

Section V, Part B.2c. Page 18,663 Column 2, 1st Paragraph - EPA is seeking comment on the derivation of the proposed MCLG for PFOS, its determination that PFOS is Likely to be Carcinogenic to Humans and whether the proposed MCLG is set at the level at which there are no adverse effects to the health of persons and which provides an adequate margin of safety. EPA is also seeking comment on its assessment of the noncancer effects associated with exposure to PFOS and the toxicity values described in USEPA (2023c).

NHDES Comment - We applaud US EPA for reevaluating the human health risk assessments (HHRAs) of PFOA and PFOS since its prior assessment in 2016. The current HHRAs included in the proposed rule incorporated several new studies, as well as re-evaluated and reinterpreted previous animal toxicity studies and human epidemiological studies cited in the 2016 assessment (EPA, 2016). The re-evaluations recommend new Reference Doses (RfDs) and Cancer Slope Factors (CSFs) for PFOA and PFOS. We request that EPA provide additional clarification for several components of its HHRAs for PFOA and PFOS.

Relative to the non-cancer HHRAs (Page 18656, Column 2), EPA provided extensive details to support its benchmark dose model to derive the points of departure (PODs) for PFOA and PFOS. However, there remains a lack of clarity around EPA's justification for assuming the populations in several of the studies, especially the Faroe Island population, are representative of the broader population and not already representative of highly sensitive segments of a general population. While some might dispute the use of these study populations entirely, we do not agree that such confounding is justification for complete dismissal of epidemiological findings from uniquely designed studies. However, we are suggesting that EPA clarify its justification of assuming these populations are representative of the broader populations relative to the selection of benchmark responses. Improved transparency around EPA's interpretation of its own guidance for these chemicals will improve confidence in the recommendation for PFOA, PFOS, other PFAS, and likely other chemicals that EPA could apply such interpretations to. In a similar theme, EPA could improve clarity by providing examples of other contaminants where it has applied similar benchmarks to epidemiological studies with similar confounding factors.

EPA Response: The commenter supports the conclusions of the EPA's toxicity assessments for PFOA and PFOS but requested clarification on the EPA's rationale for study selection. The commenter particularly highlighted the study reporting reduced antibody response in Faroese children, specifically seeking clarification on representativeness of the study population. Descriptions of the EPA's considerations for other antibody response studies during study selection are provided in section 4.2.2 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-053296 in section 4.2.2.2.4 in this *Response to Comments* document and Doc. #1774, SBC-053430 in section 4.2.1.4 in this *Response to Comments* document. Additionally, the EPA outlined considerations for selecting studies for dose-response analysis in the draft and final toxicity assessment appendices (USEPA, 2023f; USEPA, 2023a; USEPA, 2024a; USEPA, 2024b; see Section A.1.11.1). At the time of rule proposal, there were a limited number of studies examining antibody responses in children from the United States, and those providing estimates of changes in antibody response in children did

not provide enough data to include in dose-response modeling (e.g., Pilkerton et al., 2018). Since publication of the draft toxicity assessments, a study reporting anti-rubella immunity in U.S. children has also been published, further supporting and strengthening the potential relevance and weight of evidence of antibody response as an endpoint for the U.S. population (Zhang et al., 2023). The EPA has since quantitatively considered this new study for POD derivation, as described in Section 4 and Appendix E of the Final Human Health Toxicity Assessment for PFOS (USEPA, 2024c; USEPA, 2024b).

4.2.2.2.4 Use of Studies Reporting NHANES Data

3M Company (Doc. #1774, SBC-053288)

(2B) Lack of appropriate analytical techniques when using NHANES to create population metrics

As described above, proper analysis of NHANES data requires the use of sample weights to produce correct estimates of means, percentiles, and other descriptive statistics. As acknowledged in an EPA supporting document (see e.g. page F-23 of USEPA 2023b) many of the papers forming the foundation of the potential association between PFOA/PFOS and serum cholesterol did not clearly indicate whether the required NHANES sampling weights were used in their analyses. Despite EPA acknowledging this fact, EPA did not appropriately classify these publications for study quality (see e.g., Figure 3-34 on pages 3-159 through 3-161 of USEPA, 2023d). Subsequent analyses use a number of studies with study quality (high/medium/low) as a metric for the degree of confidence that can be attributed to the study finding (see e.g. Table 3-8 on pages 3-185 through 3-189 of USEPA 2023d). EPA, for example when reviewing the Dong et al. 2019 study, ignored good data and statistical practice when assigning quality scores. An independent analysis of Dong et al. indicates the analysis approaches and data practices used by Dong were flawed and the findings unsupportable. See Section 6.5).

EPA Response: The commenter asserted that the EPA's study quality evaluations did not account for sampling weights for studies that used NHANES data. The EPA disagrees with this comment and points out that the Analysis domain specifically notes when weights were used in analyses (see Appendix A (USEPA, 2024a; USEPA, 2024b)). The EPA did not receive an independent analysis of Dong et al. (2019) from the commenter and therefore, the EPA cannot respond to the commenter's claims about this study. Further consideration of the EPA's use of Dong et al. (2019) study results are provided in section 4.2.2 of this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-053296 in section 4.2.2.2.4 in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053207)

i. EPA relied on studies that used outdated and uncorrected NHANES data and did not conduct its own analysis or verify data accuracy

Many of EPA's conclusions related to non-cancer health impacts rely on previously published papers that used data sets that were ultimately rejected by the National Health and Nutrition Examination Survey (NHANES), the reporting entity, because they did not meet NHANES data quality requirements. EPA has largely relied on previously published statistical relationships between PFAS compounds and health outcomes that rely on NHANES data. NHANES regularly updates all its datasets, which in turn affects any previous quantitative analyses.72 In 2021 and 2022, the NHANES Biospecimen Program processes were reevaluated to monitor quality control after a procedural error was identified. Following a comprehensive review of all surplus sample datasets generated between 1999 and 2018, NHANES modified certain data files to remove 15-20% of PFAS records that were initially included in error because it said that data did not meet program standards. Revised files were released in April 2022 (CDC 2022). 73

While EPA notes the possibility of NHANES data updates, without conducting additional analyses, EPA cannot understand the ramification of these updates. EPA has not provided details on the data used in its analyses, or the year class of the data and it is thus very likely that EPA findings using NHANES are based on uncorrected data. Best practice is for EPA to provide details on the data updates incorporated into its models.

In short, any and all previously published analyses EPA relies on that use NHANES PFAS data contain an unknown number of errors, which invalidates the published statistical relationships.

EPA Response: The commenter misleadingly implied that all the analyses considered by the EPA for its "conclusions related to non-cancer health impacts" relied on datasets "rejected" by NHANES because they allegedly did not meet data quality requirements.

The commenter noted that NHANES updates its datasets and cited revised files published by the Centers for Disease Control and Prevention (CDC) in April 2022, which removed "15-20% of PFAS records." The commenter incorrectly implied that this had a large impact on data reported for PFOA and PFOS. In actuality, as the CDC/National Center for Health Statistics (NCHS) program states, "no data values were altered" as a result of this removal (e.g., see https://wwwn.cdc.gov/Nchs/Nhanes/2017-2018/SSPFAS_J.htM). The revisions affected various, but not all, NHANES cycles between 1999-2019 and "survey weights were adjusted" (https://www.cdc.gov/exposurereport/whats_new_121522_1.html). Data for PFOA and PFOS were not necessarily impacted by these revisions. In fact, "for each analyte included in this data file, it was determined that overall and for stratified sex, age, and race/Hispanic origin groups, the updated file using the new sample weights resulted in an estimate within the 95% confidence limit calculated using the original file and sample weights," which does not refer to PFAS serum concentrations at all. Thus, the EPA concluded that the presented data met agency data quality standards.

The commenter also claimed that CDC/NCHS revisions in 2021-2022 mean that data published before these revisions were inaccurate. According to the summary provided by CDC on the NHANES website linked by the commenter, revisions were only made to update rounding for imputed 2-(N-Methyl-perfluorooctane sulfonamido) acetic acid values (see

https://www.cdc.gov/exposurereport/whats_new_121522_1.html). These revisions were applied to the 1999-2000 and 2003-2004 cycles. Adjustments were not made to either PFOA or PFOS data; thus, the commenter's assertion that analyses were based on uncorrected data is not factually correct.

The commenter lastly incorrectly claimed that the EPA did not provide information on what NHANES data were used in its analyses. On the contrary, the EPA provided information on NHANES data included in dose-response analyses in Appendix E of the draft and final toxicity assessments for PFOA and PFOS (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b). For example, section E.1.2 of PFOA Appendix E relays how PFAS biomonitoring data from cycle 2015-2016 of NHANES was used in dose-response analyses for LBW (USEPA, 2024a). Section E.1.3 in PFOA Appendix E describes the use of the updated NHANES data in dose-response analyses of cholesterol levels (USEPA, 2024a). Finally, section E.1.4 outlines the use of NHANES data in dose-response analyses for liver outcomes (USEPA, 2024a). All of the necessary information was provided for the commenter to understand how NHANES data were incorporated into the analyses. The EPA also notes that the MCLGs for PFOA and PFOS were not ultimately based on NHANES analyses, so the commenter's concerns regarding NHANES data are irrelevant to the MCLGs derived as part of this NPDWR (see section 4.1.5 of the EPA response in this *Response to Comments* document).

3M Company (Doc. #1774, SBC-045700)

The United States Environmental Protection Agency (EPA) has published a series of quality control (QC) and best practice guidelines for program development and project development (USEPA 1992, 2002), data quality objectives (USEPA 2003, 2006), and good statistical practice (USEPA 2006). EPA has also published approved methods and software for calculating benchmark doses (BMD) and their uncertainty (USEPA 2012, 2022) which have been developed into an interactive web site. These guidelines are intended to ensure that the resulting decisions made by EPA meet standards based on the best available science, including reproducibility of results, appropriate data treatment, ensuring representative data, and accurate identification and quantification of true risk to human populations and environmental metrics.

However, the methods and procedures used by EPA to support the National Primary Drinking Water Regulation Rulemaking (the "Proposed NPDWR") did not follow these established procedures, and lack good data practice, good statistical analysis practice, consistency of methods and models, and the ability to replicate analytical results.

In the following sections we provide specific examples of where EPA is lacking good practice in its selected quantitative approaches and provide examples of inappropriate practices and issues not addressed by EPA in the proposed rule.

Below, we demonstrate key statistical issues in the Proposed NPDWR using references to the rulemaking and supporting documents, describe how the issues impact the validity of the

Maximum Contaminant Level (MCL), reference EPA support documents with examples, explain that EPA is required to meet its own guidance and specifications, and provide examples from National Health and Nutrition Examination Survey (NHANES) illustrating the issue.

Background on NHANES

NHANES is a program of studies administered by the Centers for Disease Control and Prevention (CDC) to produce vital and health statistics for the United States. Since 1999, this cross-sectional survey has been a continuous program that examines a nationally representative sample of about 5,000 different people each two-year sampling period (located in 15 counties across the country). NHANES collects demographic, socioeconomic, dietary, and health-related data and conducts a comprehensive medical examination which consists of blood work, dental, and physiological measurements. Beginning with NHANES 1999–2000, PFAS and associated compounds have been measured in some (but not all) NHANES participants. NHANES employs a multiyear, stratified, clustered design to create a nationally representative sample of the US civilian, noninstitutionalized US population; however, NHANES purposely oversamples certain demographic groups to increase the reliability and precision of health status indicator estimates for those groups. This survey design results in each sampled person not having an equal probability of selection and thus sample weighting is needed to produce correct population estimates of means, percentiles, and other descriptive statistics.

Lack of appropriate analytical techniques when using NHANES data

As described above, proper analysis of NHANES data requires the use of sample weighting variables to produce correct estimates of means, percentiles, and other descriptive statistics. EPA acknowledged in its supporting document "Economic Analysis for the Proposed Per- and Polyfluoroalkyl Substances National Primary Drinking Water Regulation Appendices" (see (USEPA 2023b), page F-23) that many of the papers forming the foundation of EPA's analysis ofthe relationship between PFAS and serum cholesterol did not clearly indicate whether the required sampling weights were used in their analyses. Despite acknowledging this fact, EPA did not give these publications appropriate classifications for study quality (*see e.g.* Figure 3-34 on pages 3-159 through 3-161 of (USEPA 2023d)). EPA chose studies where data analyses did not meet EPA guidance and good practice guidelines. Therefore, these studies were of low quality. Subsequent analyses by EPA in the support documents use the number of studies with study quality (high/medium/low) as a metric of certainty of the relationship (*see e.g.* Table 3-8 on pages 3-185 through 3-189 of (U.S, 2023d)), giving an incorrect sense of the relationship between PFOS concentrations and cholesterol.
We highlight these misclassification errors of study quality for cholesterol but the same issue applies to any and all analyses that include NHANES data without confirming use of appropriate sample weighting variables and must be corrected.

EPA Response: The commenter claimed that the EPA did not follow its own guidance on best statistical and quality control practice, specifically using the EPA's treatment of NHANES

data as an example. Please see section 4.1.2 of the EPA response in this *Response to Comments* document. Additionally, the commenter stated that the EPA did not appropriately characterize NHANES studies in study quality evaluation due to lack of adjustment for sampling weights. While the EPA agrees consideration of sampling weights is an important aspect of NHANES data analysis, the EPA disagrees that these publications were not given appropriate study quality classifications. The EPA considered whether NHANES, or other studies using complex sampling strategies, appropriately accounted for sampling design in the Analysis domain (see Appendix A, USEPA, 2024a; USEPA, 2024b). Studies that did not describe their approach to address complex sampling strategies were rated as Deficient in the Analysis domain. The study quality evaluation framework was adapted from the *Systematic Review Protocol for the PFBA, PFHxA, PFHxS, PFNA, and PFDA IRIS Assessments* which notes that a reviewer's confidence judgment be made by considering all domains, and that there are "no predefined weights for the domains." (USEPA, 2021a). The IRIS Handbook further states "[w]hile limitations specific to the usability of the study for dose-response analysis are useful to note for informing those later decisions, they do not contribute to the study confidence classifications" (USEPA, 2022a). While studies that did not account for sampling strategies may not be appropriate for POD derivation, they are still informative to hazard ID. Additionally, the analytical approach to examining NHANES data is ubiquitous throughout the epidemiological literature, and a lack of description of adjusting for sampling weights does not necessarily mean they were unaccounted for in analyses.

3M Company (Doc. #1774, SBC-053290)

3. NHANES data important to PFAS and Health Outcomes are frequently changed and/or modified.

NHANES regularly updates datasets which have PFAS concentration variables, changing the values or excluding data that do not meet program standards. Some of these changes occur relatively soon after the datasets have been released and are posted on the NHANES news website (see https://www.cdc.gov/nchs/nhanes.htm and https://www.cdc.gov/nchs/nhanes/archive_new_nhanes.htm). In 2021 and 2022 the NHANES Biospecimen Program processes were reevaluated to monitor quality control after a procedural error was identified. Following a comprehensive review of all surplus sample datasets generated between 1999 and 2018, NHANES modified certain data files to remove records that were initially included in error and did not meet program standards and revised files were released in April 2022 (Source: Update to Tables Associated with Revised NHANES Biospecimen Program Data Files see https://www.cdc.gov/exposurereport/whats_new_121522_1.html)

From https://wwwn.cdc.gov/Nchs/Nhanes/2013-2014/SSPFAC_H.htm

Note: The NHANES Biospecimen Program processes were reevaluated in 2021 and 2022 to monitor quality control after a procedural error was identified. This error did not pose any risk of participant disclosure. Addressing this error resulted in the removal of some records from various stored biospecimen data files between 1999 and 2018 that did not meet program standards. After

a comprehensive review of all stored specimen datasets, this data file was modified to remove records (15-< 20% of records) that were initially included in error. No data values were altered. However, survey weights were adjusted. For each analyte included in this data file, it was determined that overall and for stratified sex, age, and race/Hispanic origin groups, the updated file using the new sample weights resulted in an estimate within the 95% confidence limit calculated using the original file and sample weights. However, not all possible analyses were performed. For any queries related to this dataset please email the Biospecimen Program at serumplasmaurine@cdc.gov.

While EPA notes the possibility of NHANES data updates, EPA does not provide details on the data used in its analyses, or the year class of the data. Additionally, EPA ignores that papers published prior to any updates must have used the incorrect values in their analyses and thus the conclusions are at a minimum inaccurate and at worst incorrect. EPA must provide details on whether and how data updates were incorporated into its models.

NHANES Cycle	PFAS Data First Published	PFAS Data Last Revised
1999-2000	Oct-06	Dec-22
2001-2002	-	-
2003-2004	Jul-07	Dec-22
2005-2006	Aug-09	Sep-12
2007-2008	Oct-10	Oct-13
2009-2010	Dec-11	Oct-13
2011-2012	Feb-14	Oct-14
2013-2014*	Jul-16	-
		Apr-22
2015-2016	Sep-18	-
2017-2018	Nov-20	-
*For 2013-2014, PFAS were in two different NHANES tables		

EPA does not provide sufficient detail on the data used in its analyses; therefore, it is difficult to know whether EPA is using outdated data. However, given the frequency of the updates in NHANES data, any and all publications that EPA is relying on and using NHANES PFAS data that have been previously published analyses contain an unknown number of errors. The ramification is that the analyses, the generated models, and conclusions based on uncorrected NHANES data are most certainly flawed. EPA must provide details on how the NHANES data updates were incorporated into its models, if they were incorporated at all and must update its analyses to use the most accurate datasets supplied by NHANES.

EPA Response: The commenter asserted that the EPA's analyses lacked detail on and used uncorrected NHANES data in its modeling. These assertions are inaccurate. The EPA provided detailed information at the time of rule proposal in Appendix E of the draft toxicity assessments for PFOA and PFOS (USEPA, 2023b; USEPA, 2023c). The EPA used "updated"

NHANES values, as specifically stated in Section E.1.3.1. (USEPA, 2023b; 2023c). Further other consideration on the EPA's use of NHANES data and evaluation of quality for studies using NHANES data are provided in section 4.2.2 of this *Response to Comments* document, as well as the EPA response to comment Doc. #1774, SBC-053207 and Doc. #1774, SBC-053296 in section 4.2.2.2.4 in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053456)

Some studies use publicly available information, such as NHANES, and so the data should be accessible to EPA for re-analysis. For example, EPA stated that it "re-analyzed the data using the regression models from the Dong et al. (2019; 5080195) study, together with updated NHANES data, applied to a modified hybrid model" (EPA 2023a, p. E-298; EPA 2023b, p. E-26). However, EPA does not clearly document the methods regarding reanalyses and it appears that EPA obtained the updated coefficients from correspondence with the authors of Dong et al. (2019) rather than through re-modeling (EPA 2023a p. E298; EPA 2023b p. E-26). EPA states that, for its re-analysis "An important caveat is that these calculations assume that Dong's regression model is still applicable, or at least a good approximation, for all the time periods, for all adults and for adults taking cholesterol medications, and for the recently updated NHANES data." (EPA 2023a p. E-298; EPA 2023b p. E-26), which indicates a lack of re-analysis of the underlying data and development of models, de novo. EPA did not provide additional justification for why it did not re-analyze the publicly available data. Re-analysis of the underlying data, including application of non-linear models, may provide additional insight into the uncertainties regarding dose-response relationships. A full re-analysis of the NHANES data would bolster EPA's uncertainty analysis (described in Section 7) and may provide further justification or confidence in EPA's non-traditional use of regression coefficients for BMD(L) derivation.

EPA Response: The commenter incorrectly claimed that the EPA did not utilize publicly available NHANES data in the re-analysis of data used in the regression models published by Dong et al. (2019) and suggested that the EPA did not re-analyze the data using models from Dong et al. (2019). The EPA disagrees with these comments and the quotes provided by the commenter appear to be interpreted incorrectly. The EPA corresponded with Dong and colleagues to obtain the necessary details to build the same models for re-analysis (i.e., "After correspondence with the study author", USEPA, 2023b, Sec. E.1.3.1). The EPA obtained updated NHANES data (i.e., "together with updated NHANES data", USEPA, 2023b, Sec. E.1.3.1) which included NHANES cycles that were not included in the analysis reported by Dong et al. (2019). Dong et al. (2019) utilized NHANES data from 2003–2014 while the EPA expanded the scope of this analysis and provided analyses for the periods of 1999–2008, 2003–2014, 2003–2018, and 2017–2018, which is presented in Appendix E in contrast to the commenter's claims that the EPA did not document the reanalysis (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b). Additionally, all data was updated data drawn directly from NHANES, a publicly available source. The quoted caveat provided by the commenter was added to address the point that the model used in Dong et al. (2019) was built using the 2003–2014 data, and an

assumption was made that the model was still a good approximation for other NHANES time periods considering all data were from the same source and collected in the same manner.

4.2.2.3 The EPA's Benchmark Dose (BMD) Modeling Approaches

3M Company (Doc. #1774, SBC-053230)

e. Significant Uncertainty in Benchmark Dose (BMD) Derivation Approaches Preclude Confidence in the Risk Values Calculated by EPA for Non-Cancer Endpoints

EPA also violated best practices and its own guidance when it failed to independently model and verify the underlying analyses to increase confidence and transparency in the BMDL derivation of each co-critical effect. Properly conducting BMD analysis is critical because the points of departure derived from the BMD analysis are the basis of EPA's proposed non-cancer RfDs. EPA does not transparently describe its process for key study selection or the impact of uncertainties in BMDL derivation arising from 1) the lack of consideration of pooled analyses, 2) reliance upon modeling assumptions, 3) model selection; or 4) benchmark response (BMR) 79 selection. These issues are discussed below and in detail in Appendices A and B.

i. EPA was not transparent and consistent in selecting key studies and models for BMD derivation

EPA's IRIS handbook and risk assessment best practice requires that the process for selection of key studies for use in BMD and BMDL derivation be clearly described, including identifying data quality objectives to ensure consistency and transparency. But here EPA did not propose data quality objectives, and it did not follow requirements for data quality assurance. As EPA itself has noted "[t]he strength of the DQA is that it is designed to promote an understanding of how well the data satisfy their intended use by progressing in a logical and efficient manner." (USEPA 2000c, p. 0-3). As a result of this process failure, key studies had critical deficiencies that preclude confidence in their findings and the subsequently derived regression coefficients or BMD(L)s. Dose-response models and BMD(L)s derived from poor quality or limited studies may not accurately describe the true exposure-response relationship and will therefore lead to inaccurate PODs and uncertainty in RfD derivation.

Additionally, when provided with multiple models from a given study or dataset, EPA provides minimal and inconsistent justification for selection of a single model for POD derivation. For some endpoints, EPA does provide limited justification for selection of individual models within a study; however, these justifications (e.g., selection based on p-values) are not statistically defensible nor do they align with EPA guidance for model selection (USEPA 2012). Other justifications, such as stated confidence in the BMDL or potential for confounding, are not transparently defined or consistently applied. As the range of BMD(L)s both within and among studies for a given endpoint can be uncertain, it is critical for the EPA to show a transparent model selection process to increase confidence that the POD is representative of the exposure-response and not biased towards an overestimation of risk. In other words, EPA's lack of

transparency in how it selected models could lead EPA to rely on models that overestimate risk or select PODs that are highly uncertain. In addition to the lack of transparent study and model selection, EPA did not validate or compare BMD(L)s derived from individual studies with BMD(L)s derived from pooled regression coefficients (when available). This issue is discussed in detail in Appendix A.

ii. EPA's BMD values have a high level of uncertainty

For derivation of BMD(L)s, EPA used a non-standard approach and relied on previously developed models or pre-defined regression coefficients as presented in the published literature. The use of non-standard approaches violates EPA's own guidance and means that its analyses do not accurately reflect the true underlying dose-response relationships. Traditionally, benchmark dose modeling is conducted by fitting dose-response models to mean or proportional responses at given exposures; EPA's (2012) BMDS guidance is designed for these traditional dose-response models. EPA did not independently validate or verify the published regression coefficients, nor did it transparently report the details of BMD modeling from the candidate studies. Key modeling information, as recommended in EPA's benchmark dose modeling guidance (USEPA 2012), is consistently absent from the published models, including analyses of model shape, model fit, the distribution or variance of the regression coefficients, and background [P(0)] responses. EPA did not critically evaluate the underlying response data to fill gaps in reporting of the modeling approaches or results. Therefore, EPA relied on assumptions regarding model shape, model fit, coefficient variance, model distribution, confounding, and background (or "zero-exposure") responses. Without verification of these factors, EPA cannot confirm that its assumptions are reasonable approximations of the underlying data, nor can it confirm that the estimated BMD(L)s accurately describe the dose-response. Moreover, EPA derived BMD and BMDLs from models with non-significant exposure parameters and with no consideration of model fit. EPA's benchmark dose guidance (USEPA 2012) states that modeled datasets should, at minimum, have a statistically or biologically significant dose-response trend. This issue is discussed in detail in Appendices A and B.

iii. EPA failed to demonstrate that use of a non-standard BMD approach is biologically appropriate

EPA discusses uncertainties in the draft toxicity assessments for PFOA and PFOS introduced through the use of regression coefficients (a non-standard approach) instead of response data for BMD modeling of epidemiological data. As noted above, the use of nonstandard approaches may have also led EPA to make erroneous conclusions about the relationships of exposure and effects observed in human epidemiological studies. EPA used the information from Steenland et al. (2009) to validate the use of regression coefficients; Steenland et al. (2009) was selected due to the accessibility of the mean response information underlying the regression coefficients. EPA states that the difference in BMDLs generated through use of regression coefficients instead of mean response information is less than 3-fold different and therefore acceptable; EPA has not, however, demonstrated that this relationship is consistent across PFAS compounds, endpoints, studies, or publicly available information such as NHANES. EPA did not evaluate additional

datasets with the raw data or mean response information in order to quantitatively justify that the BMDLs generated through this nontraditional approach are comparable to those generated through use of mean response information. Some of the publications relied upon by EPA, including the key study for total cholesterol (Dong et al. 2019), are based on NHANES or other publicly available information and, as such, further sensitivity analyses should have been performed using these additional studies and endpoints to provide confidence in the approach used to derive BMD(L)s for PFOA and PFOS. The uncertainty analysis conducted by EPA is not sufficient for validating its use of regression coefficients instead of response data. This issue is discussed in detail in Appendix A.

iv. EPA's BMR selections are neither adequately justified nor consistently applied

BMD modeling approaches used by EPA were non-standard and relied upon published regression coefficients. EPA did not address the inconsistency in methods and approaches used for BMD(L) calculation, nor did it thoroughly consider or evaluate the sensitivity of selected models to changes in biological cutoffs or alternative BMR assumptions. Each of the endpoints selected as critical effects by EPA (e.g., serum lipids, birth weight, and vaccine response) have widely accepted clinical cutoffs that are considered biologically significant. However, EPA did not establish that the underlying exposures are significantly associated with the measured outcomes, after accounting for confounding, or increased incidence of adverse responses such as infection or cardiovascular disease. EPA may be inappropriately applying BMRs to evaluate changes in adverse outcome probability for non-adverse effects. This means that EPA may be deriving MBDs based on arbitrary changes in responses that are not actually adverse. Additional transparency is needed in order to understand 1) the methods used by EPA to estimate background exposure and probability; 2) justifications for BMR selection; 3) the impact of using alternative BMRs based on clinical cut-points on BMD(L) derivation; and 4) consideration of the strength of association between exposure and response. Additionally, in order to derive studyspecific BMRs for Extra Risk, EPA relied on estimations of the study-specific intercepts of the study-reported regression coefficients, or slopes, in order to estimate response in an unexposed population; these estimations of the outcome probability in unexposed populations does not account for model uncertainty, variance in regression coefficients, or consideration of US population responses. Differences in BMR type, BMR sensitivity, and estimations of model intercepts (or hypothetical responses in unexposed populations) impact the estimation of the BMD(L) and subsequently derived RfD. This issue is discussed in detail in Appendix A.

v. EPA did not estimate the impact of modeling assumptions on derived BMDLs or how changes in these assumptions affect BMDL sensitivity

EPA used many assumptions to estimate BMD(L)s for changes in birth weight, immune response, and serum total cholesterol. Each assumption adds some quantifiable uncertainty to the derived BMD(L)s used for POD derivation. Using analyses of changes in birth weight as an example, variations in estimations of background exposure, BMR type, and background incidence of low birth weight may increase the derived BMDL by approximately 30% to 210%, depending on the study and assumptions. Uncertainty in the derived BMDLs, based on

assumptions required to conduct modeling, impacts confidence in the derived PODs. EPA did not quantify or discuss the potential uncertainty in the BMDLs used for POD derivation or the sensitivity of the BMDLs to changes in the underlying assumptions. This critical oversight means that the PODs EPA used to derive RfDs may have significant uncertainty making its assessment of non-cancer health effects unreliable. This issue is discussed in detail in Appendix A.

EPA Response: The commenter raised several concerns regarding the EPA's approaches to BMD derivation. The commenter stated that the assessments lacked transparency regarding selection of studies and models for POD derivation. The commenter also stated that the EPA did not propose data quality objectives, and it did not follow requirements for data quality assurance, resulting in selection of low quality studies for POD derivation and increased uncertainty. The commenter additionally stated that the EPA did not compare the derived BMDLs to those derived from pooled analyses. The EPA generally disagrees with these comments and first directs the commenter to section 4.1.2 of this *Response to Comments* document.

The EPA transparently provides an explanation of the protocol for BMD derivation and study selection in Section 2.2.1 and Appendix A section 1.11.1 of the toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b). Detailed explanation of the study selection and modeling approaches for each health outcome category are provided in Appendix E of the assessments (USEPA, 2024a; USEPA, 2024b). Additionally, when studies presented multiple models (see Appendix E section E.1 and Section 4.1.4; USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b), models were selected based on best fit rather than p-values, as the commenter incorrectly implies. Further information on model selection for the priority health outcomes can be found in Appendix E. In response to this comment, additional details regarding study selection have been added to Section 4.1.1 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024b).

The commenter additionally stated that the EPA did not compare the derived BMDLs to those derived from pooled analyses. First, the EPA did not have access to pooled analyses of epidemiological data for the critical outcomes considered. Reliance on deriving BMDLs based on pooled regression coefficient (which would be obtained from a meta-analysis, rather than a pooled analysis as the commenter misleadingly implies) is not a requirement of the EPA *Benchmark Dose Technical Guidance* (USEPA, 2012). Confidence in the BMDLs used by the EPA is increased by the large number of studies considered that report the same effect and result in similar BMDL values across populations, as well as the various modelling approaches considered by the agency and presented in Appendix E (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b).

The commenter additionally stated that the EPA did not validate the use of published regression coefficients and used non-standard modeling approaches to derive BMDLs, resulting in increased uncertainty in the modeling results. The EPA disagrees that the use of "non-standard" modeling approaches led the EPA to "erroneous conclusions about the relationships of exposure and effects observed in human epidemiological studies." It appears that the commenter

misunderstands the EPA's modeling approaches for epidemiology studies detailed in Appendix E of the draft and final toxicity assessments for PFOA and PFOS (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b). The EPA also points out the use of regression coefficients for modeling dose-response and BMD calculation is hardly a "non-standard" approach and is standard practice when using epidemiological data for risk assessment. Analyses using regression coefficients to derive PODs were sent to the SAB PFAS Review Panel for their review (USEPA, 2021b; USEPA, 2021c); the SAB did not raise this as a concern in their final report (USEPA, 2022b). In fact, the SAB provided this statement in support of consideration of regression coefficients for POD derivation: "it would seem straightforward to apply the same methodology to derive the beta-coefficients ("re-expressed," if necessary, in units of per ng/mL) for antibody responses to vaccines and other health-effect-specific endpoints. Such a coefficient could then be used for deriving PODs" (USEPA, 2022b). This approach has also been recently used in other PFAS assessments, including the EPA's draft assessment for PFDA and the approach was discussed in a subsequent peer-review report (USEPA, 2023g; USEPA, 2023h).

The EPA conducted sensitivity analyses to compare BMDs produced by the reported regression coefficients with the measured response variable (i.e., mean total cholesterol and odds ratios of elevated total cholesterol), which were presented in Appendix E of the draft toxicity assessments (USEPA, 2023b; USEPA, 2023c). These sensitivity analyses showed that BMDLs estimated using the regression coefficient and using the measured response variable were within an order of magnitude in value, which *decreased* the EPA's uncertainty in this approach. The EPA disagrees that it is necessary to show consistency of these comparisons across compounds, endpoints, studies, or publicly available information such as NHANES.

The commenter also took issue with the assumptions the EPA made about the published data when conducting BMD modeling and that the EPA "modeled data with non-significant exposure parameters." As described elsewhere in this response to comments document and as even recommended by this commenter in other sections of their comment letter, the EPA does not rely solely on statistical significance to make qualitative or quantitative conclusions in these toxicity assessments. The commenter noted that "modeled datasets should, at minimum, have a statistically **or biologically significant** dose-response trend." Thus, the EPA's reliance on studies for quantitative analyses that do not show statistically significant dose-response trends does not violate EPA guidance or methods, particularly when the EPA determined there to be biologically significant effects, as is the case for all endpoints considered for toxicity value derivation in the assessments for PFOA and PFOS (see Section 4, USEPA, 2024d; USEPA, 2024c). The commenter also stated the EPA did not verify BMD modeling conducted in the published studies which is irrelevant as the EPA independently conducted BMD modeling to derive all BMDLs and did not rely on BMDLs published in peer-reviewed journal articles and PODs in the draft or final toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c).

The commenter stated the EPA did not evaluate the sensitivity of selected models to changes in selected BMRs and that they did not understand "1) the methods used by EPA to estimate

background exposure and probability; 2) justifications for BMR selection and 3) the impact of using alternative BMRs based on clinical cut-points on BMD(L) derivation." All of this information was presented in Appendix E of the draft toxicity assessments (USEPA, 2023b; USEPA, 2023c). For example, the EPA provided sensitivity analyses comparing different BMR selections for each endpoint of interest (e.g., 5 percent vs. 10 percent BMR for ALT, 1 vs ½ standard deviation [SD] for antibody response), and also provided rationale for BMR selection in these sections, as well as Section 4.1.2 of the toxicity assessments (USEPA, 2023f; USEPA, 2023a). The EPA provided rationale for why the agency did or did not use clinical cutoffs to determine BMRs for each endpoint in these same sections. The EPA also provided discussion on uncertainties in BMDL derivation due to various study-specific aspects in Appendix E of the toxicity assessments by providing BMDLs derived from multiple studies, populations, sexes, and ages (USEPA, 2023b; USEPA, 2023c). As mentioned above, the EPA disagrees that statistical significance is a prerequisite for modeled datasets, for reasons outlined earlier in this response. Regarding the adversity of the selected critical effects, please see section 4.2.2 of the EPA response in this *Response to Comments* document. In response to this comment, the EPA has improved discussion on modeling approaches in the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

More specific responses to this commenter's concerns for particular endpoints of interest (e.g., decreased birthweight) are provided in sections 4.2.2.3.1 (antibody response), 4.2.2.3.2 (total cholesterol), 4.2.2.3.3 (ALT), and 4.2.2.3.4 (birth weight) of the EPA response in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053432)

Significant uncertainty in benchmark dose (BMD) derivation approaches preclude confidence in the toxicity values calculated by EPA for non-cancer endpoints.

As recognized by the SAB, the dose-response modeling approaches for non-cancer endpoints were not transparent and were not robust. For example, the SAB stated:

The Panel recommends that EPA provide supplemental data from the BudtzJørgensen and Grandjean (2018) publication used for BMD modeling as well the conclusions of EPA's review of the modeling in the publication, and additional rationale for the selection of specific BMDLs from this publication. Overall, it is essential that details of the BMD modeling that forms the basis of the PODs is transparently available for evaluation of the methods, approaches, and results (EPA Response to Final SAB Recommendations 2023, p. 41).

EPA did not sufficiently address SAB comments regarding dose-response modeling for Budtz-Jørgensen and Grandjean (2018a). Further, many of the uncertainties and issues described by the SAB for this particular dataset apply generally to the dose response modeling approaches applied to all key studies and co-critical endpoints. In response to SAB comments, EPA states that "EPA reviewed and reevaluated the modeling from BudtzJørgensen and Grandjean (2018) and elected to conduct additional modeling of data from this study, the results of which are provided in

Appendix E" (EPA Response to Final SAB Recommendations 2023, p. 41). EPA did not conduct additional modeling, although EPA did adjust the Benchmark Response (BMR) and approach for calculating the BMD and BMD lower limit (BMDL) based on a re-evaluation of the published models.

As part of its re-evaluation, EPA also considered additional PODs from co-critical endpoints: low birthweight and elevated serum cholesterol. However, the applied modeling approaches do not follow EPA's Benchmark Dose Technical Guidance (EPA 2012). In its derivation of PODs for immune, birthweight, and CVD effects, EPA failed to adequately consider or transparently describe several modeling considerations, including:

1) Impact of key study selection (Section 3.1)

2) Pooled or combined data analyses (Section 3.2)

3) Assumptions made due to inadequate reporting of modeling details, including (Section 3.3):

· Model shape (e.g., appropriateness of linear assumptions)

· Model fit

· Model variance or distribution of coefficients

4) Use of p-values to support model selection (Section 3.4)

5) Descriptions of model confidence and applications to key model selection (Section 3.5)

6) Impact of BMR selection (e.g., sensitivity and type; Section 3.6)

7) Impact of "zero exposure" assumptions on extra risk calculations (Section 3.7)

8) Sensitivity analyses to compare predicted versus observed extra risk (Section 3.8)

9) Approaches for selection of a single candidate BMDL for each critical endpoint (Section 3.9)

Each of these considerations impart uncertainty into model selection and impact confidence in the derived BMD(L)s.

EPA Response: The commenter incorrectly stated that the EPA did not conduct additional modeling of data reported by Budtz-Jorgensen and Grandjean (2018). In the *Proposed Approaches* documents sent to the SAB for review in 2021, (USEPA, 2021b; USEPA, 2021c), the EPA relied on the BMDLs derived in Budtz-Jorgensen & Grandjean (2018) as draft PODs for PFOA and PFOS. In response to SAB recommendations (USEPA, 2022b), the EPA reevaluated the methods used in this study and determined that they did not align with recommended methods in the *Benchmark Dose Technical Guidance* (USEPA, 2012). The EPA then conducted independent, new (i.e., "additional") BMD modeling of data from this source to derive BMDLs that were then used to develop candidate RfDs for the immune health outcome. These efforts were documented in Appendix E.1 of the draft toxicity assessments for PFOA and PFOS (USEPA, 2023b; USEPA, 2023c). The commenter noted several other perceived issues with the

EPA's modeling approaches which are presented in more detail, along with the EPA responses, under subsections 4.2.2.3.1 (antibody response), 4.2.2.3.2 (total cholesterol), 4.2.2.3.3 (ALT), and 4.2.2.3.4 (birth weight) below.

3M Company (Doc. #1774, SBC-053433)

EPA did not follow SAB recommendations regarding use of combined data analyses relative to single study estimates in developing RfD values; this is particularly impactful given the differential findings from meta-analyses relative to individual studies.

EPA did not transparently discuss its approach for selecting key studies for model consideration based on the underlying strengths and limitations, and did not validate or compare BMD(L)s derived from individual studies with BMD(L)s derived from the pooled regression coefficients (when available). Each of the key studies used for BMD(L) modeling has some uncertainty or deficiency tied to study design and analysis, limiting confidence in individual models. The SAB reflected this limitation in their recommendation that "the final choice of the health-effect specific RfDs and the overall RfD consider the strength and limitations of the data upon which each is based. A metaanalysis approach also should be considered" (EPA Response to Final SAB Recommendations 2023, p. 38).

In response to the SAB, EPA stated that it "performed a meta-analysis to evaluate associations between PFOA/PFOS exposure and effects on serum lipids, specifically total cholesterol (TC) and high-density lipoprotein cholesterol (HDLC). EPA also considered available meta-analyses while evaluating evidence of the associations between PFOA/PFOS and other health outcomes considered… EPA incorporated the results of recent meta-analyses as another line of evidence considered in the evidence integration" (EPA Response to Final SAB Recommendations 2023, p. 39). The findings of EPA's 2021 meta-analysis on serum lipids were not presented in the Draft Toxicity Assessment nor were the regression coefficients reported in the meta-analysis results considered for BMD(L) derivation.

Additionally, EPA did not consider or discuss for BMD(L) derivation pooled regression coefficients reported by meta-analyses on the effects of PFOA and/or PFOS on birthweight (Johnson et al. 2014; Verner et al. 2015; Negri et al. 2017; Steenland et al. 2018; Dzierlenga et al. 2020, as described in EPA 2023a, Table A-42 p. A-127 to A-128 and EPA 2023b, Table A-42 p. A-150 to A-151). As noted in the EPA's 2012 BMD Technical Guidance, "combining several datasets may be an option" (EPA 2012, p. 14). However, EPA did not explain its decision to evaluate individual studies instead of the pooled estimates that incorporate broader populations, increased dose ranges, and increased sample size. Although comparisons in the linear slope estimates of the EPA meta-analysis with those from Dong et al. (2019) and Lin et al. (2019) are presented in the Economic Analysis (Appendix K, Table K-3, p. K-5) in order to "assess the effects of using a key single study approach versus the meta-analysis approach to inform the exposure-response estimates" (EPA Response to Final SAB Recommendations 2023, p. 73), these comparisons neither account for the uncertainty in the slope estimates nor provide

justification for use of individual studies in lieu of the meta-analytic slope estimate for risk assessment purposes. This lack of consideration is a critical deficiency of the analyses, as the uncertainty in slope or variability in study selection may have significant impacts on BMD(L) and RfD derivation.

EPA Response: The commenter incorrectly stated that the EPA did not consider SAB recommendations to consider "combined" data analyses rather than single study estimates when deriving RfDs. Regarding how the EPA responded to SAB comments, please see section 4.1.3 of the EPA response in this *Response to Comments* document and the EPA's Response to SAB Comments document (USEPA, 2023d). Specifically, the EPA refers the commenter to response I.E5B.2 which discusses the EPA's meta-analysis for serum lipid effects (USEPA, 2023d). The EPA reiterates that the SAB stated, "A meta-analysis approach also *should be considered*," which the EPA has done; the SAB did not recommend a meta-analysis approach over single study estimates (USEPA, 2022b). The SAB similarly did not recommend the EPA "validate" BMDLs derived from single studies to BMDLs derived from "pooled regression coefficients," as incorrectly implied by the commenter (USEPA, 2022b).

The commenter additionally stated that the EPA did not provide justification for selecting PODs from individual studies over PODs derived from meta-analyses. The EPA has subsequently updated the final toxicity assessments for PFOA and PFOS and notes that the results from meta-analyses were not selected for POD derivation for several reasons, including lack of available meta-analyses for certain critical health outcomes, and uncertainty introduced when re-expressing regression coefficients based on combined analyses of multiple studies (e.g., estimated in the log-scale) to the normal scale for BMD and BMDL estimation (USEPA, 2024d; USEPA, 2024c). Additionally, in other analyses supporting this rulemaking, the EPA did use results from meta-analyses (see USEPA, 2024e). The EPA also refers the commenter to Appendix E.1.5 of the toxicity assessment for PFOA which outlines comparisons between pooled and single study CSF estimates (USEPA, 2024a).

The commenter briefly reiterated their assertion that the EPA did not adequately describe its approach for selecting key studies for model consideration, which are presented as more detailed comments, along with the EPA responses, under subsections 4.2.2.3.1 (antibody response), 4.2.2.3.2 (total cholesterol), 4.2.2.3.3 (ALT), and 4.2.2.3.4 (birth weight) below.

3M Company (Doc. #1774, SBC-053434)

The BMD values generated by EPA are associated with a high level of uncertainty; EPA should better address SAB recommendations, re-assess, and re-model BMD analyses to characterize and reduce uncertainties in model parameters, fit, and variance resulting from model assumptions.

As stated by the SAB, "it is essential that details of the BMD modeling that forms the basis of the PODs is transparently available for evaluation of the methods, approaches, and results" (EPA Response to Final SAB Recommendations 2023, p. 41). For derivation of BMD(L)s, EPA relied on previously developed models or pre-defined regression coefficients as presented in the

published literature. Although EPA responded to the SAB that "Based on recommendations from the SAB, EPA reviewed and reevaluated the modeling from Budtz-Jørgensen and Grandjean (2018) and elected to conduct additional modeling of data from this study" (EPA Response to Final SAB Recommendations 2023, p. 41), EPA did not conduct additional modeling of the Faroe Islands cohorts. "Regression coefficients (β) and their standard errors (SE) were computed by EPA from the published BMDs and BMDL based on a BMR of 5% decrease in the antibody concentration in Table 1 of Budtz-Jørgensen and Grandjean (2018, 5083631)" (EPA 2023a, p. E-269; EPA 2023b, p. E-1). EPA did not independently validate or verify the published regression coefficients using raw or mean response data from Budtz-Jørgensen and Grandjean (2018a), nor has it transparently reported the details of the BMD modeling based on this study. Additionally, EPA did not transparently report the details of BMD modeling from the candidate studies for other critical endpoints, including changes in serum TC or LBW.

Many of the key studies and published models used by EPA do not report critical modeling information, including analyses of model shape, model fit, or the distribution or variance of the regression coefficient. Despite EPA (2012) guidance, EPA did not critically evaluate the underlying response data to fill gaps in reporting of the modeling approaches or results. As stated by EPA BMD Guidance (2012), "for data evaluation in general, data (responses and doses) should be validated to the extent possible. For example, the original source should be examined, if possible, and any deliberate omissions of dose groups or subjects by the authors should be recognized and their basis understood." (EPA 2012 p. 14). Without validation of the modeling approaches and considerations, EPA may continue to replicate errors or omissions made in the original publications relied on for POD derivation. The lack of independent model validation, lack of access to information regarding the underlying data and model distributions, and lack of evaluation of the impact of these uncertainties limits confidence in the derived PODs.

Ideally, EPA would use raw or mean response data in order to perform independent doseresponse analysis. EPA BMD guidance states that, "from a modeling standpoint, the most desirable form for [continuous] data is by individual" (EPA 2012, p. 27). However, without access to the raw data, use of individual data is not possible and EPA used the uncertain regression coefficients instead. EPA noted, "BMD modeling of regression coefficients results in a nontraditional BMD, where the BMR is associated with a change in the regression coefficient of the response variable rather than the measured biological response variable. As a result, there is some uncertainty about the biological relevance of this non-traditional BMD associated with a regression coefficient." (EPA 2023a, p. 6-16; EPA 2023b, p. 6-14). EPA determined to use regression coefficients for POD derivation because it asserts that they are associated with changes in biological response and are biologically meaningful. EPA used uncertainty analyses in an attempt to address uncertainties regarding the biological relevance of the non-traditional BMD. However, as described further in Section 7, the uncertainty analysis (which evaluates the impact of using regression coefficients in lieu of response variables) is limited in scope and does not convincingly show concordance between BMD(L)s derived from the two approaches.

EPA Response: The commenter repeated their claims regarding modeling of Budtz-Jorgensen and Grandjean (2018), which the EPA responded to in the response to comment Doc. #1774, SBC-053432 in section 4.2.2.3 in this *Response to Comments* document. The commenter briefly reiterated concerns that the EPA did not adequately describe its approach for modeling critical studies, which are presented as more detailed comments, along with the EPA responses, under subsections 4.2.2.3.1 (antibody response), 4.2.2.3.2 (total cholesterol), 4.2.2.3.3 (ALT), and 4.2.2.3.4 (birth weight) below.

Responses to the commenter's repeated concerns regarding the EPA's use of summary statistics provided by peer-reviewed journal articles when conducting BMD modeling is also presented in these sections. Notably, if the EPA was able to derive RfDs from the critical studies, then all "critical modeling information" was provided, in contrast to the commenter's claims. If critical modeling information was missing, the EPA would not have been able to derive RfDs from those studies. This was actually the case for some *high* and *medium* confidence studies, which are discussed in Section 4.1 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c).

Regarding the EPA's use of the best available science and EPA guidance in these assessments, please see section 4.1.2 of the EPA response in this *Response to Comments* document. The commenter claimed that the EPA did not follow the *Benchmark Dose Technical Guidance* (USEPA, 2012) when deriving PODs, but provided an example, "deliberate omissions of dose groups or subjects by the authors should be recognized and their basis understood," that does not apply to any of the studies selected for POD derivation in these assessments (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

3M Company (Doc. #1774, SBC-053435)

Because of its reliance on the published literature, EPA makes assumptions in the doseresponse modeling that stem from limitations in study reporting. Specifically, when using the reported regression coefficients as the basis for BMD(L) derivation, EPA must accept the assumption that a linear dose-response is most appropriate and therefore extrapolate risk estimates based on those linear assumptions. One exception includes the BudtzJørgensen and Grandjean (2018a) analyses, which include both linear and piecewise-linear models; the authors state that a logarithmic function was attempted "however, the steep slope at very low doses may be biologically implausible, and the logarithmic curve did not show a better fit to the data compared to the piecewise linear shape" (Budtz-Jørgensen and Grandjean 2018a). Without additional information regarding the underlying data or mean response, EPA cannot consider additional non-linear dose-response shapes that may better reflect the proposed mechanisms of action for each critical endpoint. EPA did not discuss available mechanistic information to inform or support the appropriateness of the linear dose-response shape assumptions. Linear models may be either under- or over- predicting risk, depending on the mechanism of action. Current methods in benchmark dose modeling are moving away from selection of single dose-response models and are instead moving towards the use of Bayesian Model Averaging (BMA) In order to account for

uncertainties in model determination and to reflect the underlying distribution of possible models (e.g., EFSA 2022). EPA guidance for BMD assessment notes that model averaging is a useful tool for "synthesis of risk estimates" and "may help to account for the impact of model uncertainty on risk estimates" but urges selection of a single "well-fitting and plausible model" due to challenges in application of model averaging (EPA 2012, p.36). Re-analysis of either the raw data or the mean response attributed to specific doses or dose ranges would enable EPA to consider multiple dose-response relationships with model averaging approaches to better reflect intra- and inter-model uncertainties.

An additional limitation in the approach used by EPA is the lack of consideration of model fit, especially in the region of the BMR and BMD(L). In response to an inquiry by EPA, the study authors have provided unpublished information and analyses, including relevant SAS code and model output for the linear and piecewise linear models shown in BudtzJørgensen and Grandjean (2018a). Notably, the model outputs (provided in BudtzJørgensen and Grandjean 2018b, 2022a, 2022b) reveal that the fitted models have adjustedR 2 values ranging from 1.0 – 3.7%, which indicates that 96-99% of the total variance in antibody response is not explained by the linear models. Furthermore, the PFAS exposures are only a subset of several predictors in the models suggesting that the percentage of variance explained by exposure alone is even smaller than 1.0-3.7%. Neither BudtzJørgensen and Grandjean (2018a) nor EPA address the low adjusted-R 2 values, and R2 information was omitted from the Budtz-Jorgensen and Grandjean (2018a) publication. Instead, EPA states that "no information was available to judge the fit of the model in the range of the BMDLs" (see e.g., EPA 2023a pp. E-274-275, E-277, E-282, E-285; EPA 2023b pp. E-5, E-8, E-13, E-16) for each of the diphtheria and tetanus response models presented by Budtz-Jørgensen and Grandjean (2018a). Given that the adjusted-R 2 values explain so little of the underlying antibody response, additional data visualizations and sensitivity analyses are needed to substantiate the modeling approach. Residual plots would be useful for assessing the existence of outliers and potentially influential observations that affect the slope (coefficient) estimates and resulting model fit. Examination of residuals and visual inspection of the fit of the models and underlying data are recommended by EPA BMD Technical Guidance (EPA 2012, p.39, 45, 50), and EPA recommends to "further reject models that apparently do not adequately describe the relevant low-dose portion of the dose-response relationship" based on those examinations (EPA 2012, p.39).

EPA Response: The commenter asserts that the EPA has to make certain assumptions about the shape of the dose-response because of reliance on the published literature. First, please see section 4.1.2 of the EPA response in this *Response to Comments* document. Additionally, the commenter themselves indicate by citing Budtz-Jørgensen and Grandjean (2018), that the published literature does report observations about the dose-response relationship. Further, analyzing the mean response data is not always feasible in epidemiology studies, unlike in most toxicology studies, hence reliance on regression slopes that come from models that might not necessarily be linear. While current methods are being developed that use Bayesian Model Averaging, these approaches are not necessarily standard approaches to agency human health

toxicity assessments, nor is there any implication they are a required consideration the *Benchmark Dose Technical Guidance* (USEPA, 2012).

The commenter stated that the EPA did not consider model fit, particularly in the region of the BMR and BMDL. The commenter claimed that the linear models do not account for 96-99 percent of the total variance in antibody response reported by Budtz-Jørgensen and Grandjean (2018). The commenter recommended additional analyses to substantiate the modeling approach, such as residual plots. The EPA disagrees with these comments as they appear to misinterpret the analyses that the EPA presented in Appendix E of the draft toxicity assessments for PFOA and PFOS (USEPA, 2023b; USEPA, 2023c).

More specifically, Budtz-Jorgensen and Grandjean (2018) fit three different model types, logarithmic, linear, and piece-wise linear models, for each PFAS and each antibody response. The EPA used the best fitting models for BMD estimation. Given that there was no indication of non-linear departure from the low-dose linear slopes, and that the BMDs and BMDLs were within the range of observed exposure values, there was no evidence of lack of fit in the low-dose region. Budtz-Jorgensen and Grandjean (2018) stated that,“"[a]ll dose-response models had normally distributed residuals with a homogeneous scatter”" This provides further evidence of support for the fit in the low-dose (i.e., BMR and BMDL) region as a lack of fit there would not be expected to yield such evidence. As such, the EPA should not reject these models as described in the *Benchmark Dose Technical Guidance* (USEPA, 2012) and does not require additional analyses to substantiate the approach.

Additionally, in the modeling the commenter describes above, R^2 is not simply a measure a model fit as the commenter seems to imply. Indeed, an R^2 statistic reflects the degree of variance in the outcome explained by the covariates in the model. Regardless of how good the model fit is, the R^2 statistic fluctuates with the number of covariates. What is important (and not reflected by the R^2 statistic) is the effect of the exposure on the outcome, adjusted for potential confounders, when modeled appropriately to ensure that the best model fits the data.

3M Company (Doc. #1774, SBC-053436)

EPA did not transparently describe its process for determining model confidence. Model diagnostic plots were not included in EPA’s draft toxicity assessments of PFOA and PFOS. These diagnostic plots would be useful to validate the model assumptions.

For some models, in order to use the reported regression coefficients for BMD(L) derivation, EPA needed to pool distributional information across cohorts, or make other assumptions regarding the standard deviation (SD) of the regression coefficients due to limitations in the author-reported coefficient variance. As noted by EPA in its 2012 guidance, “in some cases, a measure of variability is presented for the control group only and this information might be used for modeling by making an assumption, for example, that the variance in the exposed groups is the same as in the controls. However, this assumption may not be correct, and the modeling of the data and calculation of the confidence limits will not be as reliable or precise as when the

variance information is available for individual groups" (EPA 2012, p.13). Although the EPA guidance may not be directly applicable to the "non-traditional" approach used by EPA in this risk assessment, due to the lack of controls and traditional exposure groups, the risk of adding imprecision through assumptions of underlying variance still applies. As noted by BudtzJørgensen (2007), "benchmark calculations depend on a reliable estimate of the true response variation (Gaylor and Slikker 2004) and are therefore also sensitive to measurement uncertainty in the response" (Budtz-Jorgensen 2007). BMD(L)s derived for immune responses, changes in serum TC, and LBW are all impacted by these uncertainties. For example, in order to apply a BMR of 0.5 SD change in the distribution of log2 tetanus antibody concentrations reported by Budtz-Jørgensen and Grandjean (2018a), EPA pooled distributional information from two different cohorts reported by Grandjean et al. (2012, 2017). In order to derive the pooled SD, EPA made assumptions that the log2-transformed values are comparable to a normal distribution with a width of 1.35 SDs (EPA 2023a, Appendix E p. E-277). In other examples, EPA re-expressed β coefficients of Chu et al. (2020), Govarts et al. (2016), Sagiv et al. (2018), Starling et al. (2017), Wikstrom et al. (2020), and Yao et al. (2021) as a per ng/mL coefficient based on the reported study-specific medians and 25th and 75th percentiles (see summary in EPA 2023a Table E-15 and EPA 2023b Table E-13). As an example, in order to re-express the β coefficient into a usable form, EPA states that "Given the reported study-specific median…and the 25th and 75th percentiles…of the exposure from Chu et al. (2020, 6315711), EPA estimated the distribution of exposure by assuming the exposure follows a log-normal distribution… Then, EPA estimated the 25th -75th percentiles at 10 percentile intervals of the exposure distribution and corresponding responses of the β coefficient" (EPA 2023a, p. E-291-292; EPA 2023b, p. E-19). In other studies (e.g., Timmerman et al. 2021), the study findings are reported as a percent difference (given some magnitude of change in exposure) and EPA used assumptions to convert the percent change in response to an estimated slope. Although the approaches used by EPA for regression coefficient and variance estimation may be reasonable approximations, uncertainties in the BMD(L) derivation are introduced through this approach. EPA did not conduct sensitivity analyses to evaluate the impact of its pooling, transformation or re-expression of the underlying evidence on 1) the accuracy of the estimations used or 2) the sensitivity of the models to either small or large perturbations from each model assumption.

EPA Response: The commenter stated that the EPA did not provide information about how model confidence was determined and did not provide "diagnostic plots." The commenter also highlighted several quantitative assumptions the EPA made while conducting dose-response modeling of epidemiological data, incorrectly claiming that the EPA did not conduct sensitivity analyses to evaluate these assumptions and that there may be uncertainty associated with these assumptions. The commenter implied that the EPA was not following agency guidance when conducting these modeling efforts. The EPA disagrees with these assertions.

Many of the comments above are repeated by this commenter. Regarding modeling assumptions including pooled variances and percentiles, please see the EPA response to comment Doc. #1774, SBC-053296 in section 4.2.2.2.4 in this *Response to Comments* document. For discussion specific to critical studies modeled for the antibody response to vaccination endpoint and

decreased birthweight endpoint, including discussion on sensitivity analyses, please see the EPA responses in subsections 4.2.2.3.1 and 4.2.2.3.4, respectively. Regarding model confidence and diagnostic plots, see the EPA response to comment Doc. #1774, SBC-053437 in section 4.2.2.3 in this *Response to Comments* document.

Additionally, agency guidance recommends multiple approaches to data analysis in order to accommodate instances when the agency may not have the optimal data available (e.g., variance information available for individual groups; USEPA, 2012). The use of an approach using assumptions does not contradict agency guidance, nor should it be considered incorrect or flawed.

3M Company (Doc. #1774, SBC-053437)

EPA subjectively and inconsistently selected which dose-response models to carry forward in risk assessment; EPA should provide a more transparent and objective description for the selection of individual models from key studies.

When provided with multiple models for a given dataset, EPA provides minimal and inconsistent justification for selection of models within a study. EPA BMD guidance recommends provision of a rationale for study selection and for the selection of endpoints, stating, "thorough justification of the choices made to support the chosen approach and values should be presented." (EPA 2012, p.40). Similarly, EPA recommends providing the rationale for individual model selection, in addition to reporting the estimation procedure, model parameters, goodness-of-fit, log-likelihood, AIC, and standardized residuals (EPA 2012, p.40). EPA does not report these considerations in its rationales for model selection in the PFOA and PFOS documents.

In some examples, such as immune response, EPA states that it chose the models from the Budtz-Jørgensen and Grandjean (2018a) analysis that do not control for other PFAS based on a comparison of p-values for tetanus and diphtheria responses without consideration of other important factors (such as controlling for other PFAS) or model fit in the region of the BMD(L). Although EPA (2012) BMD Technical Guidance does not require or proscribe categorization of model confidence, EPA provided statements regarding its confidence in the BMD(L)s derived from some of the selected key studies; these statements are largely based on the estimated level of uncertainty in the BMD(L) attributed to confounding. However, EPA does not transparently describe its process for categorization of confidence in the derived BMD(L)s nor does it provide criteria for systematic and transparent judgment of model confidence. Additionally, EPA does not clarify how these determinations of confidence in the BMD(L) are defined or applied in the justification for model selection. Nor does EPA consistently provide these determinations of BMDL confidence for all models or endpoints (e.g., serum lipids or birth weight). The lack of transparency and consistency in EPA's approach for judging BMD(L) confidence limits may further preclude robust evaluation of EPA's decisions to select individual BMD(L)s from single studies for POD derivation.

Although there is no transparently described approach for determining model confidence, EPA does provide some limited justification for its determination of high, medium, or low confidence for the models based on the Budtz-Jørgensen and Grandjean (2018a) studies. For example, the dose-response between PFOS measured at five years and diphtheria responses was judged to be "medium" because "confidence was diminished by the potential confounding in the main effect – even though there was low confounding of the BMDL" (EPA 2023b, E-13). This statement is not informative regarding the types of confounding that are considered (by EPA) to be problematic. EPA does not provide reasoning for its judgment that the impact of confounding on the BMDL is "low", despite the knowledge that other unexplained factors play a significant role in the observed dose-response; in this example, the adjusted-R 2 of this model (see Budtz-Jørgensen and Grandjean 2018b, 2022a, 2022b) only accounts for 3% of the variability in diphtheria antibody response, regardless of whether or not PFAS is included in the model. Therefore, approximately 97% of the modeled response is explained by other factors, including potential confounders. In another example, EPA stated that confidence in the BMDLs derived from the model evaluating dose-response between PFOS measured at age five years and tetanus was "low" because "confidence was diminished by the non-significant fit for PFOS ($p = 0.12$) and stronger potential confounding in the main effect – even though there was moderate confounding of the BMDL" (EPA 2023b, E-6). EPA made a similar judgment in confidence based on the statistical significance for the POD derived from Timmerman et al. (2021); specifically, EPA states that the POD based on Timmerman et al. (2021) "is identified with lower confidence" because the BMDL is "based on a non-significant PFOA regression parameter" (EPA 2023a, p. E-279). These statements are problematic, as the statistical significance of the dose-response relationship, alone, should not be a driving factor for determination of study or POD quality. Rather, the lack of statistical significance should be considered as part of the overall weight of evidence to determine whether the endpoint is appropriate for consideration as a critical effect.

EPA did not provide transparent justifications for its judgements regarding study and BMD(L) quality, the potential for BMD(L) confounding, and the specific confounders that are being considered when making judgements regarding the potential for "low", "moderate", or "high" potential for confounding. It is assumed, based on current documentation, that EPA is using the impact of inclusion or exclusion of other PFAS in the models for determination of confounding potential, as these are the only explanatory variables that are clearly varied between models in the Budtz-Jørgensen and Grandjean (2018a) publication. EPA should not solely consider the inclusion or exclusion of other PFAS when evaluating the impact of confounding. However, if confounding by coexposure is the sole consideration when making judgments regarding the confidence in derived BMD(L)s, EPA is not applying these considerations consistently. For example, EPA judged the BMDL from the model evaluating PFOS exposures at age 5 in relation to tetanus antibodies as "low confidence" because the "effects of PFOS in the single-PFAS model are attenuated when log2[PFOA] is included in the model" (EPA 2023b, p. E-2). However, similar relationships were observed for PFOA exposures at age 5 in relation to tetanus antibodies, with EPA stating that "effects of PFOA in the single-PFAS model are attenuated when log2[PFOS] is included in the model" (EPA 2023a, p. E-270). But EPA judged the

confidence in the BMDLs of the latter comparison as "high". Therefore, EPA must consider other factors when judging confidence. Although EPA provided some partial justifications, EPA did not explicitly or transparently describe the process for deriving these judgments. Specifically, EPA notes the observed attenuation is potentially driven by confounding of PFOS on PFOA effect, however it postulates that physiological confounding (or the correlation between biomarkers measured from the same blood test) may also be a factor (see EPA 2023a, p. E-276 as an example). These additional confounders and limitations and their impact on model uncertainty and confidence are not clearly addressed.

Moreover, the confidence in the BMDLs derived from other publications for other endpoints (including the co-critical endpoints of CVD and birth weight) are not explicitly described. For example, EPA states that "Although the hybrid approach has several advantages {Crump, 1995, 2258}, few details were provided in Dong et al. (2019, 5080195) on several important aspects of this approach or on other key issues, including the definition of the unexposed reference group, the distribution of PFOS or TC values in this group, model fit (e.g., the fit of linear vs. non-linear models), the impact of potential confounders, or the potential role of reverse causality" (EPA 2023a, p.E-298;2023b p. E26). However, EPA does not provide any statement regarding the confidence in its BMD(L) derived from the models of Dong et al. (2019) and whether these limitations would reduce confidence in the derived POD.

EPA Response: The commenter asserted that the EPA provided inconsistent justification for model selection in BMD modeling. The EPA disagrees with this assertion as the agency provided modeling details and outputs for every modeled study in Appendices E of the draft PFOA and PFOS toxicity assessments (USEPA, 2023b; USEPA, 2023c). Model selection is specific to each critical outcome and each analysis, rather than a "one fits all" approach, which is why the discussion may appear inconsistent across endpoints. For transparency, the EPA added a table outlining the modeling approaches at the beginning of Appendix E of the final toxicity assessments (USEPA, 2024a; USEPA, 2024b).

After careful consideration of the commenter's point on the lack of consistent presentation of confidence in the derived PODs, to ensure the EPA's results are most readily understandable and interpretable by the scientific community, regulators, and members of the public, the EPA added descriptions of factors that could influence confidence in the derived PODs consistently across the modeled studies, including for Dong et al. (2019), in Section 4.1.4 and Appendix E of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b) and removed language that unintentionally gave the impression of "prescribing" confidence to specific PODs. Some factors that the commenter claimed the EPA did not consider (e.g., confounding) were addressed during study quality evaluations (see Appendix A, USEPA (2024a) and USEPA (2024b)). For more information, see sections 4.1.1 and 4.1.2 of the EPA response in this *Response to Comments* document.

Regarding modeling of immune endpoints (i.e., from Budtz-Jørgensen and Grandjean (2018) and Timmerman et al. (2021)), see section 4.2.2.3 of the EPA response in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053438)

EPA provided inadequate justification for BMR assumptions selected for its derivation of BMDLs.

EPA did not thoroughly consider or evaluate the sensitivity of selected models to changes in biological cutoffs or alternative BMR assumptions, despite its statement that they took "statistical and biological considerations into account to select the BMR" (EPA 2023a, p.4-14; EPA 2023b, p.4-13).

EPA states that it used methods for BMR selection consistent with the BMD Technical Guidance (EPA 2012). Specifically, "the BMD and 95% lower confidence limit on the BMD (BMDL) were estimated using a BMR intended to represent a minimal, biologically significant level of change. The Benchmark Dose Technical Guidance {U.S. EPA, 2012, 1239433} describes a hierarchy by which BMRs are selected, with the first and preferred approach being the use of a biological or toxicological basis to define what minimal level of response or change is biologically significant… For continuous responses, the preferred approach for defining the BMR was to use a preestablished cutoff for the minimal level of change in the endpoint at which the effect is generally considered to become biologically significant (e.g., greater than or equal to 42 IU/L serum ALT in human males {Valenti, 2021, 10369689}). In the absence of an established cutoff, a BMR of 1 SD change from the control mean, or 0.5 SD for effects considered to be severe, was generally selected." (p. 4- 14)" (EPA 2023a, p.4-14; EPA 2023b, p.4-13). Each of the endpoints selected as critical effects by EPA (e.g., serum lipids, birth weight, and vaccine response) have widely accepted clinical cutoffs that are considered biologically significant (described in detail in Section 2). For example, the World Health Organization (WHO, 2009, 2018), describes a minimum amount of circulating anti-tetanus or anti-diphtheria antibody that ensures protection from infection. This amount is dependent on the assay used to measure serum antibody levels (WHO, 2009, 2018). "It is assumed that a circulating diphtheria antitoxin level of 0.01 IU/mL, as determined by the neutralization test… provides basic clinical immunity against disease" (WHO, 2009) "whereas antitoxin concentrations of at least 0.1– 0.2 IU/mL are defined as positive [protective] when ELISA [enzyme-linked immunosorbent assay] techniques are used for the assessment" (WHO, 2018). However, because infections have occurred in people with antibody levels within the protected range, EPA made the conservative determination that "there is no accepted definition of an adverse level of change or clinical cut-off for reduced antibody concentrations in response to vaccination. Therefore, EPA performed the BMDL modeling using a BMR equivalent to a 0.5 SD change in log2-transformed antibody concentrations, as opposed to a fixed change in the antibody concentration distributions" (EPA 2023a, p. 4-15; EPA 2023b, p. 4-14). Additionally, birthweights below 2500g are clinically described as "low" by WHO (Cutland et al. 2017) and serum cholesterol >240 mg/DL is clinically considered "high" (NCHS 2019). EPA considers these clinical cutoff-points in its derivation of the BMRs and subsequent BMD(L)s for TC and birth weight effects, but not vaccine response. EPA describes the rationale for its selection of BMRs in Table 4-2 (EPA 2023a,b). However, the rationales for BMR selection for some critical endpoints are incomplete (i.e., the rationale for selection of a 5% extra risk

BMR for decreased birthweight associated with PFOA is incomplete) or poorly justified (e.g., selection of 5% extra risk because the standard BMR of 10% extra risk for TC would "result in a highly improbable doubling of risk"). At a minimum, careful descriptions of the rationale for derivation of BMRs, especially when deviating from the standard approach, and sensitivity analyses to consider the impact of consideration of clinical significance on vaccine response are needed. As an example, for changes in birthweight, use of an 0.5 SD change as the BMR instead of a 5% increase extra risk may increase the BMDL by up to 150-210%, depending on the study.

EPA Response: This comment repeats the commenter's claims that the EPA did not provide adequate rationale or follow agency guidance when selecting BMRs for dose-response modeling. The EPA disagrees and has provided substantial explanation and documentation in its peer-reviewed toxicity assessments. Please see section 4.1.2 of the EPA response in this *Response to Comments* document. Please also see the EPA response to comment Doc. #1774, SBC-053230. All rationale for BMR selection, including citations to the EPA guidance, are presented in Section 4.1.2 and Appendix E of the final PFOA and PFOS toxicity assessments (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

3M Company (Doc. #1774, SBC-053439)

EPA did not account for a "zero exposure" or control group or the impact of using logarithmically transformed distributions when calculating "extra risk" BMRs.

Due to the limitations of reporting in the available epidemiolocal data, EPA may be overestimating background risk when calculating the BMR. EPA used BMRs of 0.5 SD for deriving BMD(L)s for immune responses and 5% extra risk (based on a hybrid approach) for deriving BMD(L)s based on low birth weight and increases in serum cholesterol. However, the BMR calculations are dependent on the probability or mean response at baseline, defined mathematically as "zero exposure". Therefore, EPA may not be appropriately accounting for background exposures to PFAS in their BMR and BMD(L) calculations.

Extra Risk is "a measure of the proportional increase in risk of an adverse effect adjusted for the background incidence of the same effect" (EPA 2012, p. 70). Extra risk calculated as a function of the probability of response at zero dose [P(0)] and the probability of response at a specified dose [P(d)]. The background probability [P(0)] is what is used to define the adverse response (i.e., a 5% or 10% change in probability or response from P(0)). Specifically, the equation used to estimate the BMR is:

Extra Risk = [P(d) – P(0)] / [1-P(0)]

Estimation of a BMR based on a standard deviation change in response is also based on the mean at zero dose. Specifically, a BMR based on standard deviation is defined as:

SD Response = m(0) + (BMRF x Standard Deviation)

where m(0) is the mean response at 0 dose and the BMRF is typically either 1 or 0.5, depending on the sensitivity of the chosen endpoint or BMR.

EPA acknowledges the potential impact of this assumption of zero exposure in the extra risk calculation in its comments to SAB, stating, "EPA selected the hybrid approach for POD derivation (Crump, 1995). The hybrid approach defines a benchmark response (BMR) for continuous outcomes, where the BMD corresponds to the dose yielding a specific increase in the probability of an adverse response, compared with zero background exposure [emphasis added]. The more commonly used standard deviation (SD)-definition of the BMR for continuous data is simply one specific application of the hybrid approach (U.S. EPA, 2012)" (EPA Response to Final SAB Recommendations 2023, p. 23).

EPA Response: The commenter incorrectly stated that the EPA's approach may not account appropriately for background exposures in using BMRs of 0.5 SD and 5 percent extra risk in hybrid approaches. The EPA disagrees with this comment. Please see the EPA response to comment Doc. #1774, SBC-053453 in section 4.2.2.3.4 in this *Response to Comments* document, which discusses this assertion in the context of decreased birthweight. This response applies across all endpoints for which the EPA used the hybrid modeling approach.

3M Company (Doc. #1774, SBC-053440)

For the immune and serum cholesterol effects, EPA does not describe use of an approach that is comparable to the one used for evaluating changes in birthweight; for these effects EPA does not evaluate or report the impact of background exposures on estimations of extra risk using an alternative tail probability. Calculation of an intercept based on a normal cumulative distribution function is described for the BMD(L) estimation from Dong et al. 2019; but this approach is not reproducible nor is it applied to the models for Steenland et al. (2009) or Lin et al. (2019). EPA does not describe why it considers this a potential limitation of the birth weight studies but not for other estimations of excess risk. An example of where this estimation is critical is in evaluation of the selected BMR for increases in TC. EPA states that a 10% BMR for calculating a BMDL based on increases in serum TC would be inappropriate for use because it would cause a "highly improbable doubling of risk" (see EPA 2023a,b; Table 4-2) because "the percentage of U.S. adults aged 20 and older with total cholesterol ≥240 mg/dL is 11.5%" (EPA 2023b, p. 4-15). However, EPA does not adequately account for background exposures and must use assumptions to estimate a "zero response" probability. Given the known impact of key factors such as diet, exercise, and genetics on cholesterol (see Section 2.3), any model that predicts a doubling of background hypercholesterolemia in the US population with 10% extra risk should be heavily scrutinized. EPA did not conduct additional analyses to adjust for background exposures to PFAS and the impacts those may have on derivation of BMRs based on extra risk for TC and for immune responses. Without these adjustments, there is a possibility that the BMRs based on an extra risk approach may be overestimating the probability of the outcome at the BMD.

In addition to the uncertainties associated with the potential impact of estimations of background exposure in BMD(L) derivation, there are additional uncertainties in the appropriateness of BMDLs derived from lognormally distributed data. As stated by EPA in its BMDS User Guide, "when response data is lognormally distributed, the BMR Types acquire different meanings… Using log-transformed responses in the analysis is not recommended" because "Data interpretation when using log-transformed responses will not be the same as when using the natural-scale response values. Indeed, the models— when "transformed back" to the natural scale—will not correspond to any of the standard BMDS models." (EPA 2018, p.20-219 ; EPA 2020, p. 5710; EPA 2022, p. 7511). Additionally, "interpretation of the BMD will not correspond to simple expressions (e.g., if the BMR is set equal to a relative deviation of 10%, that relative deviation will be assessed on the log-scale and so will not yield BMD or BMDL estimates that correspond to a 10% change in the original mean responses)" (EPA 2018, p. 21; EPA 2020, p. 5712; EPA 2022, p. 7513). Therefore, because EPA is using the log2-transformed BMD and BMDL reported by Budtz-Jorgensen and Grandjean (2018a) for derivation of BMDLs based on vaccine responses, extreme caution must be used when converting these values to un-transformed BMD(L)s and comparisons of extra risk for justification of individual BMD(L) selection. EPA did not re-evaluate its estimates of extra risk of immune responses by accounting for the lack of a true control and the log-normal transformation of the data.

EPA Response: The commenter asserted that the EPA did not use a modeling approach for TC and antibody response that is comparable to the one used for evaluating changes in birthweight. As noted in previous responses (Doc. #1774, SBC-053437), the EPA did not use the same method for BMD derivation across endpoints or studies. The approaches used by the EPA are dependent on the data and models available and on the critical outcome evaluated, including whether there are accepted clinical thresholds for adversity or biological significance. However, in response to this comment, the EPA improved discussion on the modeling approaches used for various studies (e.g., explanations for differences between modeling approaches for Dong et al. (2019), Steenland et al. (2009), and Lin et al. (2019)) in Appendix E of the final toxicity assessments (USEPA, 2024a; USEPA, 2024b).

The EPA also added detail in section 4.1.2.3 in the final toxicity assessments regarding BMR selection for cardiovascular effects (USEPA, 2024d; USEPA, 2024c). For the cardiovascular endpoint of increased serum TC in adults associated with PFOA or PFOS exposure, the BMD and the BMDL were estimated using a BMR of 5 percent extra risk from the biologically significant adverse serum TC concentration. The EPA presents PODs estimated using a 10 percent BMR for comparison purposes in Appendix E.1.3 (USEPA, 2024a; USEPA, 2024b).

Regarding the EPA accounting for extra risk and lack of "true control," please see the EPA response to comment Doc. #1774, SBC-053453 in section 4.2.2.3.4 in this *Response to Comments* document. Regarding how the EPA modeled specific endpoints, see sections 4.2.2.3.1, 4.2.2.3.2, 4.2.2.3.3, and 4.2.2.3.4 of the EPA response in this *Response to Comments* document.

With respect to uncertainties in using lognormally distributed data, the EPA clarifies that the BMD modeling for Budtz-Jørgensen and Grandjean (2018) utilized models with log-transformed

antibodies as the response variable, while PFAS exposure was untransformed and included additional covariates in the models. In this paper, they defined the BMR using percent relative deviation based on log-transformed antibodies. In contrast, EPA defined the BMR using standard deviation of log-transformed antibodies. These BMR definitions were constructed such that BMD and BMDL are solely functions of the regression coefficients of untransformed exposure. Importantly, these approaches allow for calculation of BMD/BMDL even in cases where raw data is not available. In the context of epidemiological studies where the raw individual participant data is unavailable and often protected, the BMR definition using log transformed responses is a solution. Because of this approach, the BMD and BMDL is calculated for log-transformed antibody responses. In other words, the goal is to determine the dose associated with a specific level of change in the log-transformed response, rather than the does related to a change in the original natural-scale response. The step of transforming back to natural scales is therefore deemed unnecessary. The commenter is also referred to the EPA response to SBC-053230.

3M Company (Doc. #1774, SBC-053441)

EPA did not consistently evaluate the impacts of BMR selection through sensitivity analyses of expected or extra risk or transparently describe its processes for evaluating the findings of its analysis, which may lead to inappropriate elimination of candidate studies.

Critically, EPA did not perform checks on extra risk estimations for all endpoints, or even for all studies or models considered within an endpoint. There is also no guidance for adjustment or consideration when these checks show that the conservative BMR selection is not a good estimate of 5% extra risk (e.g., the Timmerman et al. 2022 models). If these analyses are going to be used to justify selection of specific BMD(L)s, as is the case for the immune response models, EPA failed to transparently and consistently show the purpose of these assessments, describe the implications of their findings, and apply these assessments for all derived BMD(L)s.

EPA did not re-calculate many of these comparisons of the BMR with extra risk predictions, as EPA fails to account for critical factors in BMR derivation, including: 1) the lack of a true "control" or unexposed group and the impact of exposures in the background populations on extra risk calculations; and 2) the impact of use of log transformed data for modeling purposes and BMD derivation. Moreover, EPA made assumptions regarding the distributions of the populations with immune responses below the 0.1 IU/mL cutoff and did not independently verify the percentage of the population with values below the cutoff value with the raw data or study authors.

EPA Response: The commenter appears to misunderstand the modelling that the EPA conducted to support the PFOA and PFOS toxicity assessments. The extra check for the BMR selection is not applicable for endpoints where an clinical cutoff for extra risk already exists (e.g., ALT, BWT, and TC). In the case of modelling for tetanus, an endpoint for which an accepted clinical cutoff does not exist, these extra checks were performed for the study that

moved forward for RfD derivation in order to demonstrate that the selected BMR of ½ SD provides a reasonably good estimate if 5 percent extra risk. Additionally, these checks are just one factor in selection of the candidate studies and are not the sole determining factor. To further increase transparency, the EPA added rationale to explain selection of candidate RfDs (see section 4.1 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c)).

The commenter asserts that the EPA did not evaluate the impacts of BMR selection through sensitivity analyses. The EPA disagrees with the commenter and points to the sensitivity analyses presented in Appendix E of the assessments (USEPA, 2024a; USEPA, 2024b). For example, for the ALT and total cholesterol endpoints, BMD analyses were presented for two different BMRs. The EPA also disagrees with the commenter's claim that the EPA failed to account for "critical factors in BMR derivation." The EPA assumes that the commenter actually meant "BMD derivation." The intercept in a regression analysis represents the mean response in an unexposed population (see details in Section E.1 of USEPA (2024a; USEPA, 2024b)). To illustrate the impact of log transformed data for modelling purposes, the EPA added additional sensitivity analyses for total cholesterol and ALT modeling (see USEPA, 2024b).

In referring to assumptions regarding the distributions of the populations with immune responses below 0.1 International Standard UnitIU/mL, the commenter referred to an example the EPA included for illustrative purposes only, based on methods described in the *Benchmark Dose Technical Guidance* (USEPA, 2012). The purpose of this example is to illustrate how changes in the BMR relate to a shift in the population response compared to the 0.1 IU/mL antibody level. The calculations provided demonstrate that the EPA's selected approach to modeling is reasonable.

3M Company (Doc. #1774, SBC-053442)

EPA does not transparently describe its approach for selection of a single candidate BMDL for RfD derivation.

For each critical endpoint, EPA selects the BMDL used for derivation of outcome-specific RfDs from the range of modeled BMD(L)s. The process for selection of the outcomespecific BMDL for RfD estimation is not clearly described nor is systematic guidance provided. For example, EPA states that it used the BMDLs from models of anti-diphtheria responses in 7-year-old children from Budtz-Jorgensen and Grandjean (2018a) for derivation of the immune RfD for PFOS because "1) the response reported by this study reached statistical significance, and 2) the analysis considered co-exposures of other PFAS" (EPA 2023b, p. 4-47). For PFOA, EPA states that "EPA considered both [BudtzJorgensen 2018 and Timmerman 2021] as they both represented the low-dose range of effects across immunological endpoints and provided data regarding sensitive populations (i.e., children)" (EPA 2023a, p. 4-42). This statement is in direct contradiction with the summary of modeling results from Appendix E that states EPA selected POD of 3.47 ng/mL based on the model of anti-tetanus measurements at age seven from

BudtzJorgensen and Grandjean (2018a) because "the comparison POD of 2.26 ng/mL is considered lower confidence because it is based on a non-significant PFOA regression parameter" (EPA 2023a, p. E279). Based on these justifications, EPA may be placing undue importance on use of statistically significant regression parameters instead of considering the full weight of evidence, consistency, and the clinical relevance of the endpoints used for POD derivation. Moreover, EPA does not clearly describe how the disparate BMD(L)s derived from those two studies (shown in Table E-6), or within BudtzJorgensen and Grandjean (2018)'s models of multiple ages and considerations, are condensed to a single RfD. EPA does not consider the implications that, for the immune response, the BMDL derived from the Timmerman et al. (2021) model with non-significant associations (or regression coefficients) between exposure and response generated a BMD(L) that was more sensitive than those derived from Budtz-Jorgensen and Grandjean (2018a). This example shows why determination of confidence in the BMD(L)s based on statistically significant regression parameters is problematic. Judgments of BMD(L) confidence should not be based on the statistical significance of the regression parameters and should, instead, be based on the transparency and quality of the underlying doseresponse data.

For other endpoints, EPA uses the modeling confidence as the sole reason for selecting a BMD(L) for RfD derivation. As an example, "the RfD for increased TC from Dong et al. (2019, 5080195) was ultimately selected for the health outcome-specific RfD for cardiovascular effects as there is marginally increased confidence in the modeling from this study." (EPA 2023b, p.4-48). The process for determining confidence in the modeling is not clearly described or transparent, which reduces confidence in the resulting RfD if POD selections were based on poorly supported determinations of modeling confidence. EPA did not provide clarity and transparency in the process for making scientific judgments in order to increase confidence in the derived RfDs.

EPA Response: The commenter stated that the EPA did not transparently describe BMDL selection and that the EPA relied too heavily on statistical significance for BMDL selection. The EPA disagrees with these comments. The EPA, as illustrated in Appendix E, clearly used effect estimates that show both significant and null associations in modelling (USEPA, 2024a; USEPA, 2024b). The EPA also considered study confidence ratings in the study-specific statistical analyses (described in the study-specific risk of bias assessments available in Section 3 of the toxicity assessments (USEPA, 2024d; USEPA, 2024c)), when selecting a certain BMDL. The EPA agrees that judgments of BMD(L) confidence should not be solely based on the statistical significance of the regression parameters or models and should, instead, be based on many factors including but not limited to statistical significance, such as the transparency and quality of the underlying dose-response data (USEPA, 2012), which is exactly the approach that the EPA took in the PFOA and PFOS toxicity assessments. As the commenter pointed out, the EPA provided rationale across several parts of the draft toxicity assessments and appendices, primarily Chapter 4 and Appendix E (USEPA, 2023f; USEPA, 2023a; USEPA, 2023b; USEPA, 2023c), that described important assessment conclusions including critical study selection, model selection, POD selection, and RfD selection. In response to this comment, the

EPA has updated these sections in the final toxicity assessments to more clearly present this rationale (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

The EPA discusses considerations of the weight of evidence, consistency, and the clinical relevance of the endpoints used for POD derivation in responses under subsections 4.2.2.3.1 (antibody response), 4.2.2.3.2 (total cholesterol), 4.2.2.3.3 (ALT), and 4.2.2.3.4 (birth weight), as well as section 4.2.2 of the EPA response in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053443)

EPA failed to quantitatively assess uncertainty in the RfDs derived for PFOA and PFOS as requested by the EPA SAB.

EPA discusses uncertainties in the draft toxicity assessments for PFOA and PFOS that were introduced through the use of regression coefficients instead of response data for BMD modeling of epidemiological data (EPA 2023a,b). In addition, EPA provides a qualitative discussion of the uncertainties in the chemical-specific parameters used to model or calculate an external dose (i.e., human equivalent dose) from internal serum PFAS concentrations. Comments regarding the limitations in the EPA's uncertainty assessment of BMD and PBPK modeling are described below.

Uncertainties in estimation of PODs through use of BMD modeling

EPA's discussion regarding uncertainties in the POD estimates derived from BMD models is limited to a discussion of the use of regression coefficients instead of measured response variables (see Section 6.6.3 of EPA 2023a,b). Additional limitations described in Section 3 were not addressed, including the impacts of:

· Key study selection

· Selection of regression coefficients within key studies

· Background exposures

· BMR sensitivity and selection

· Linear assumptions

· Coefficient distribution assumptions

· Use of non-adverse outcomes (e.g., increases in TC instead of hypercholesterolemia)

· Use of log-transformed data or coefficients

EPA's uncertainty analysis is inadequate; EPA fails to prove that use of a non-standard BMD approach is biologically appropriate.

EPA Response: The commenter incorrectly stated that the EPA did not implement SAB feedback regarding RfD derivation and that the EPA did not quantitatively address uncertainty.

The EPA disagrees SAB feedback was not implemented, and further discussion of the EPA response to the SAB can be found in section 4.1.3 of the EPA response in this *Response to Comments* document. Quantitative analyses of uncertainty were presented at the time of rule proposal as sensitivity analyses in Appendix E and F of the draft toxicity assessments for PFOA and PFOS (USEPA, 2023b; USEPA, 2023c) and are still available in the final toxicity assessments (USEPA, 2024a; USEPA, 2024b).

The commenter claimed that the EPA did not consider various sources of uncertainty in BMD modeling of critical effects and critical studies. The EPA disagrees and directs the commenter to the EPA response to comment Doc. #1713, SBC-053371 in section 4.2.2.1 for discussion of how the EPA addressed uncertainties throughout the assessments, as well as section 4.2.2 of the EPA response in this *Response to Comments* document regarding the adversity of the selected critical effects. Please see the EPA response to comment Doc. #1774, SBC-053444 in section 4.2.2.3 in this *Response to Comments* document regarding modeling of regression coefficients.

3M Company (Doc. #1774, SBC-053444)

As described in Section 3, EPA relied on published regression coefficients to derive BMD(L)s for CVD, TC, and immune response effects. This approach of "modeling of regression coefficients results in a nontraditional BMD, where the BMR is associated with a change in the regression coefficient of the response variable rather than the measured biological response variable. As a result, there is some uncertainty about the biological relevance of this non-traditional BMD associated with a regression coefficient." (EPA 2023a p.6-16; EPA 2023b p.6-14). However, "EPA modeled these regression coefficients using the same approach that EPA used to model for studies that reported measured response variables" (EPA 2023a p. 6-16; EPA 2023b p.6-14). EPA tested this assumption that the regression coefficients were comparable to measured response variables through evaluation of a single study for which both regression coefficients and measured response data were available: Steenland et al.'s (2009) publication regarding increases in serum cholesterol associated with PFOA and PFOS exposures.

EPA used data provided by Steenland et al. to compare BMD(L)s generated through the reported regression coefficients with BMD(L)s generated through use of measured response variables (associated with deciles of exposure). For PFOS, the BMDL estimates were more than two-fold different, with measured BMDLs of 9.52 ng/L from the approach using regression coefficients and 26.39 ng/L from the approach using the measured response. EPA does not address these differences, and instead states that "The two BMDL estimates from the two approaches are within an order of magnitude, less than a 3-fold difference, and the RfD allows for an order of magnitude (10-fold or 1,000%) uncertainty in the estimate. Therefore, EPA is confident in its use [of] regression coefficients as the basis of PODHEDs" (EPA 2023b, p.6-14). However, for PFOA, EPA states that modeling of the response variable did not generate viable models, and therefore it could not make a quantitative comparison (see EPA 2023a, p. 6-16). EPA instead uses the findings from the PFOS comparison to justify comparability of the BMDLs for PFOA.

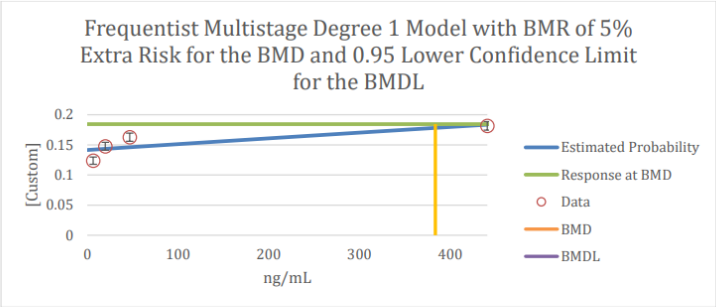
EPA does not discuss the limitations and adjustments made to enable comparison of the dose-response of the measured responses to traditional dose-response models using BMDS in the main documentation of the toxicity assessments (see 2023a p.E-301; 2023b p. E-29). For PFOA and PFOS, no viable models were identified when EPA modeled all 10 of the regression coefficients and deciles of exposure. To fit a dose-response, EPA used only the five lowest deciles and regression coefficients (EPA 2023a, Tables E-21 and E-22); however, EPA does not explain why it only considered five deciles of exposure. Upon review of the full range of reported regression coefficients (Table 3 of Steenland et al. 2009), the regression coefficient does not have a large magnitude of change between the fourth to tenth deciles of exposure range (coefficient range of 0.03 to 0.05). In order to generate a model based on a more traditional BMD approach, EPA modeled the measured response (incidence of hypercholesterolemia) reported by Steenland et al. (2009) for each quartile of exposure (EPA 2023a, Tables E-23 and E-24; EPA 2023b, Tables E-21 and E22). EPA does not explain why the measured response (hypercholesterolemia incidence) cannot be measured by decile of exposure to better match the models based on regression coefficients from the same underlying data. The measured response information is dichotomized, which means that the models used by EPA's BMDS are not directly comparable to those used for evaluation of the continuous regression coefficients. Models provided in the suite of continuous model options (e.g., exponential models) may also be more flexible and able to fit the sharp increase in response modeled in the lower dose regions (as reported by Steenland et al. 2009). An approach that would provide more confidence in model comparisons would be to compare BMD(L)s generated from the regression coefficients (by decile) with the mean TC (by decile).

Regardless, EPA states that none of the BMD(L)s generated through modeling of the measured responses for PFOA were viable, as the goodness of fit p-values were all < 0.001 (EPA 2023a, Table E-24). Recreation of the modeling approach used by EPA shows that the poor fit is in part driven by the small estimates of allowable variance in hypercholesterolemia incidence due to the relatively large sample size (n = approximately 11,400 per quintile of exposure); the large sample size limits the acceptable range of error in model prediction (see Figure 1 as an example). However, in contrast with EPA's statements, one model (the Dichotomous Hill model) does adequately fit the underlying data when a BMR of 5% Extra Risk is selected (P = 0.812; Figure 1). The BMDL05 generated for this model is 4.74 ng/mL PFOA, which approximates the BMDL05 of 4.25 ng/mL PFOA generated from the regression coefficients. This single fitted model does have high levels of uncertainty (e.g., a BMD/BMDL ratio >3), which accounts for the derivation of a comparatively low BMDL. These models indicate a potential for high model dependence, with all other models estimate BMDL05s ranging from 381 to 436 ng/mL PFOA (Figure 1). Critically, EPA does not report that the estimated BMD and BMDL for all models except the dichotomous hill are higher than the mean estimate of the largest quartile of exposure. This means that EPA is extrapolating beyond the range of observable data. Additionally, EPA's BMD Technical Guidance states that "in some cases, most of the available model fits may not appear to be adequate on the basis of goodnessof-fit p-values alone, i.e., p-values are less than 0.1. Some of these less adequate fits may be satisfactory when other criteria are taken into account (including the nature of the variability of the endpoint, visual fit, and residuals in the

most relevant region of the data range.); expert judgment is useful in these cases" (EPA 2012, p.33). In this example, the scaled residuals for the region near the BMD in each of the models are within acceptable ranges. EPA did not consider the impact of its non-traditional use of BMDS for analysis of epidemiological data with large sample sizes or discuss the fit of these models based on criteria other than goodness-of-fit.

Model selection creates another area of uncertainty in POD derivation, however EPA does not address the range of BMDLs generated through use of the mean or elevated serum models. For example, the range of BMDL0.5SD generated for TC from the regression coefficients ranged from 24.66 to 31.37 ng/mL PFOS (See EPA 2023b Table E-20) and the range of BMDL0.5SD generated from modeling the incidence of hypercholesterolemia in ranged from 14.27 to 40.29 ng/mL PFOS. (see EPA 2023b Table E-22). Note that the selected BMDL of 9.52 ng/mL PFOS, which is used for the uncertainty analysis comparisons and described in Table E-25 is not presented in the BMDS modeling summaries. EPA did not provide additional clarity on how it derived the value of 9.52 ng/mL. From the measured response models, EPA selected a BMDL05 of 26.39 ng/L PFOS based on the log-logistic model. No rationale for the model selection is provided. For these analyses, EPA did not consider use of model averaging to incorporate the full range of model uncertainty and avoid selection of a single model.

In order to make the current evaluation of Steenland et al.'s data more robust, EPA should have considered use of the mean TC measurements per decile of exposure to make a direct comparison with the exposure bands represented in the regression coefficient models. Use of the mean TC measurements per decile would allow direct comparison of the measured endpoint; as it currently stands, EPA's uncertainty analysis compares increases in serum TC measurements against the odds of having elevated TC. Use of mean TC (a continuous variable) would also allow EPA to consider the same suite of models between approaches including additional flexible model shapes (e.g., exponential models) that may better fit the observed dose-response.



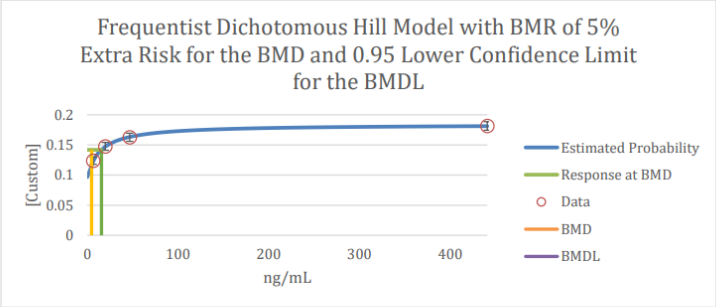


Figure 1. Benchmark-dose model examples from Steenland et al. (2009), with exposure measured in quartiles of exposure, show that the BMD(L) is highly model dependent and uncertain (BMD/BMDL ratio >3); response is incidence of hypercholesterolemia.

BMDS and other epidemiological models that dichotomize exposure measurements cannot account for the impact of ranges of exposures within the defined quartiles, deciles, or other categorical groupings of exposure. Inadequate consideration of the range of exposures associated with measured responses adds additional uncertainty. EPA did not use comparable dose ranges (e.g., deciles of exposure) in both analyses in order to improve comparability between the models used for testing and validating their approach; use of comparable dose ranges would minimize uncertainty in their comparisons of BMD derivation approaches. Additional analyses, such as the use of the Epidemiological Analysis function provided by BBMD (www.benchmarkdose.com), would allow for incorporation of uncertainties in exposure or consideration of exposure ranges provided within the epidemiological literature. Regardless of which modeling tool or approach is used, EPA did not consider the impacts of exposure uncertainty in BMD models based on epidemiological data.

EPA selected the information from Steenland et al. (2009) due to the accessibility of the mean response information underlying the regression coefficients. EPA states that the difference in BMDLs generated through use of regression coefficients instead of mean response information is less than 3-fold different and therefore acceptable, however EPA has not demonstrated that this relationship is consistent across endpoints, studies, or PFAS compounds. EPA did not evaluate additional datasets with the raw data or mean response information in order to quantitatively justify that the BMDLs generated through this nontraditional approach are comparable to those generated through use of mean response information. Some of the publications relied upon by EPA, including the key study for TC (Dong et al. 2019), are based on NHANES or other publicly available information. EPA did not conduct further sensitivity analyses based on these additional

studies and endpoints to provide confidence in the approach used to derive BMD(L)s for PFOA and PFOS.

EPA Response: The commenter made numerous incorrect or immaterial claims regarding the EPA's modeling of regression coefficients and specifically the sensitivity analysis the EPA conducted, particularly to compare various types of TC data reported by Steenland et al. (2009). In general, the EPA disagrees with these claims. The commenter appears misunderstand modeling approaches for POD derivation of epidemiologic studies.

The commenter first questioned why the EPA did not model the data using all reported deciles of exposure in Steenland et al. (2009) and claimed that the EPA did not include rationale for only including the lowest five deciles. The EPA stated "BMDS 3.3rc10 was used to fit the dose response data using all deciles, no viable models were identified. To further investigate, BMDS 3.3rc10 was used to fit the dose-response data in the lowest five deciles." Therefore, quantitative analyses could not be conducted when incorporating data from all deciles. This rationale was transparently presented in the Appendix E of the draft toxicity assessments for PFOA and PFOS (USEPA, 2023b; USEPA, 2023c).

The commenter then recommended the EPA "compare BMD(L)s generated from the regression coefficients (by decile) with the mean TC (by decile)." The commenter also incorrectly claimed that the EPA did not use mean TC data in its analyses. In fact, the EPA reported sensitivity analyses for Lin et al. (2019) and Steenland et al. (2009) that addresses both of those comments, by comparing PODs derived based on either mean serum TC or increased serum TC measures reported by quintile or quartiles of exposures (USEPA, 2023b; USEPA, 2023c). Such data were not available for Dong et al., (2019) and therefore, the agency could not conduct a similar analysis for this study.

The commenter additionally stated that the EPA incorrectly determined that there were no viable model fits to provide a quantitative comparison between the regression coefficient and measured response variable approaches. The commenter stated that one model (the Dichotomous Hill model) adequately fit the data. The EPA disagrees and illustrated this in Appendix E. 1.4.2.2.2. The commenter stated their analysis had "high levels of uncertainty (e.g., a BMD/BMDL ratio >3)." A model output with a BMD/BMDL ratio > 3 is not recommended for use as a POD in the benchmark dose software (BMDS). Therefore, the EPA does not rely on BMDLs with this type or magnitude of uncertainty and argues that this is evidence that the Dichotomous Hill model does not adequately fit the data as the commenter claimed.

The commenter claimed that the EPA did not report that the "estimated BMD and BMDL for all models except the dichotomous hill are higher than the mean estimate of the largest quartile of exposure" and claimed that subsequently, the EPA was "extrapolating beyond the range of observable data." The EPA disagrees with the comment. The estimated BMD and BMDL of 4.99 and 4.25 ng/mL for Steenland et al. (2009) were shown as sensitivity analyses, thus the EPA is not extrapolating beyond the observable data.

The commenter stated that the EPA did not consider the compatibility of BMDS for analysis of epidemiological data with large sample sizes. The EPA disagrees and points out that the data from Steenland et al. (2009) were only presented as sensitivity analyses for illustrative purposes. The commenter additionally discussed the EPA's model selection, claiming that the agency did not discuss the suitability of various models based on criteria other than goodness-of-fit and did not address the "range" of BMDLs produced from the different models. Comments regarding the EPA's rationale for model selection are addressed in the EPA response to comment Doc. #1774, SBC-053437 in section 4.2.2.3 in this *Response to Comments* document.

The commenter inaccurately stated that the EPA selected "the information from Steenland et al. (2009) due to the accessibility of the mean response information underlying the regression coefficients" and noted that the EPA did not conduct these sensitivity analyses across multiple studies or endpoints. The EPA provided rationale for selecting data for quantitative analyses of Steenland et al. (2009) in Appendix E1.4.2.2 (USEPA, 2023b; USEPA, 2023c). As noted in previous responses to comments about Steenland et al. (2009), the data from Steenland et al. (2009) were only presented as sensitivity analyses for illustrative purposes.

3M Company (Doc. #1774, SBC-053445)

EPA does not estimate the impact of modeling assumptions on derived BMDLs, or sensitivity of BMDLs to changes in these assumptions.

As discussed in Section 3, EPA uses many assumptions to estimate BMD(L)s for changes in birth weight, immune response, and serum TC, including:

· Background incidence of adverse outcomes associated with changes in these biometrics

· Estimates of model intercepts based on assumptions of background exposure and model shape

· BMR selections, including type (e.g., extra risk or SD) and magnitude (e.g., 5% or 10% extra risk, or 0.5 or 1 SD)

· Linear relationships between exposure and response

· Approximations of coefficient distributions

Each of these assumptions adds some quantifiable uncertainty to the derived BMD(L)s used for POD derivation. Using analyses of changes in birth weight as an example, variations in estimations of background exposure, BMR type, and background incidence of LBW may increase the derived BMDL by approximately a minimum of 30% and a maximum of 210%, depending on the study and assumptions. Uncertainty in the derived BMDLs, based on assumptions required to conduct modeling, impacts confidence in the derived PODs. EPA did not quantify or discuss the potential uncertainty in the BMDLs used for POD derivation or the sensitivity of the BMDLs to changes in the underlying assumptions.

EPA Response: The commenter states that the EPA did not estimate the impact of modeling assumptions in BMD derivation analyses and lists a number of assumptions that are common to dose-response modeling practices (USEPA, 2012). The EPA disagrees with this assertion and points to the tables in Appendix E where the EPA shows and explains the impact of modeling assumptions and provides BMDLs for various BMRs, models, or assumptions (USEPA, 2024a; USEPA, 2024b). The assumptions listed by the commenter were outcome, data and modeling approach specific, rather than global assumption for all analyses as the commenter suggests, and thus, sensitivity analyses to evaluate impacts of every single assumption are not always feasible or needed for every study. To the commenter's example of the BMD analyses for birthweight, for example, the impact of assumptions about background exposure is presented in in Section E.1.2 (USEPA, 2024a; USEPA, 2024b).

The EPA discusses additional considerations of the impact of modelling assumptions for specific endpoints under subsections 4.2.2.3.1 (antibody response), 4.2.2.3.2 (total cholesterol), 4.2.2.3.3 (ALT), and 4.2.2.3.4 (birth weight) of this response to public comment document, as well as in section 4.2.2 of the EPA response in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053296)

6. EPA's approaches to Benchmark Dose (BMD) are insufficient and inconsistent with accepted statistical standards.

EPA's approach to BMD calculations is lacking in appropriate sensitivity testing, choice of equation, and in some cases inappropriate use of information from the original publications. We discuss below the inappropriate information use and practice utilized by EPA for BMD calculations.

(6A) EPA does not properly address statistical significance

In Appendix E, Table E-1 (USEPA 2023c, e) displays BMDs in the Budtz-Jørgensen & Grandjean (2018) paper. In Table E-1, the slope coefficient which is used to calculate the BMD is clearly not significant, nor even close to significant. EPA states that the non-significant parameter can be used to calculate the BMD and BMDL. What is not shown is that the models in Table E-1 are poor representations of the original data (which are not available for review and testing) and fit the data poorly (they have a non-significant t-statistic). Therefore, the resulting non-significant slope is not correlated with the original data, and therefore is inconsistent with the underlying science inferred by the model. We note that the unavailability of the data negates the ability to rerun the model and thereby ensure the published results are reproducible and precise. No practicing statistician would agree that a BMD or a BMDL estimated from a non-significant model including a non-significant model parameter should be used to set a standard. EPA repeats this mistake throughout the BMD calculation process.

(6B) EPA's choices regarding statistical and/or biological properties of analyzed data are inconsistent with accepted practice.

EPA clearly states that selection of the BMR for the purpose of estimating a BMD involves making judgements about the statistical and biological properties of the data set. Yet, EPA provides no analysis of the sensitivity that these choices may have on the final BMD. The choice of BMR and the choice of "extra risk" (the p(0) term in the BMD calculation) simply will not withstand scientific review without a clear association back to clinical effects on the US population. As noted in the EPA QAPP guidelines, it is bad statistical practice to make judgement calls and subsequently calculate costs and benefits, without exploring the ramifications of and sensitivity of the results to these decisions in practice.

In summary (1) EPA has not conducted a sensitivity analysis of these arbitrary BMR and p(0) terms; (2) EPA provides no scientific basis for the choice of model equation; (3) EPA provides no scientific justification for (or against) specific BMR and p(0) choices, other than to state what EPA believes is commonly used; and most importantly,(5) EPA provides no explanation or examples of how the BMD calculations relate to actual human health risk. EPA must scientifically support how these calculations result in reduced mortality on a national scale.

For example, in the below table we demonstrate BMD and BMDL outcomes using two different BMD model equations (the Budtz-Jørgensen & Grandjean (2018) model, and the EPA Hybrid method used in Dong et al.(2019)). Models with three different sets of co-variates are fit (rows of the table) for NHANES total cholesterol data. (Dong et al., 2019). The appropriate NHANES weighting functions are used to generate the model estimates (there is no mention of weights in Dong et al. 2019). The choice of the extra risk term, and the choice of BMR make a significant difference in the resulting BMD and BMDL and could highly influence the final reference dose and ultimately the MCLG. Key co-variates that possibly affect the model parameter estimates should be included in all BMD calculations, which many of the papers selected by EPA do not do. These co-variates include the presence of a cholesterol lowering drug, age, ethnicity, gender, and BMI. Note in the analysis below the wide range of BMD and BMDL values found with relatively small changes in the BMR and p(0) terms. Also note that the slope parameter (the parameter multiplied by the total cholesterol concentration) is non-significant in every model. We supply this table only to show the range of BMD and BMDL values that can occur with arbitrary values of BMR and p(0). Good statistical and scientific practice requires EPA to relate the selected BMR and p(0) terms to the endpoints of interest, which according to EPA are severe disease or mortality estimates for the US population on a national basis. We also note that EPA claims the Dong et al. (2019) model included key co-variates like those above; however, this is not noted in the actual paper.

There are many BMD model forms and analytical approaches to choose from (Budtz-Jorgensen, Keiding, & Grandjean, 2001; Crump, 1995; Liu et al., 2016; USEPA 2012, 2022; Wheeler, Cortinas, Aerts, Gift, & Davis, 2022; Wheeler et al., 2023), including regression approaches, maximum likelihood approaches, and Bayesian approaches. How EPA chose from these differing approaches was not explained. Additionally, EPA did not robustly compare results from the various model forms and statistical paradigms. Without these explanations and comparisons,

EPA's decision-making and the scientific basis for its Proposed NPDWR are not transparent and prevent meaningful comment and analysis by reviewers.

Table 2 (below) provides an examination of the sensitivity of the BMD and BMDL calculations using two different model equations, and various values of BMR and p(0). Note that for any specific model and set of co-variates, the BMD and BMDL values vary tremendously. This results in a large variance in the resulting RfD. The equations are associated and follow a specific set of progressive calculations. Uncertainty at any specific level of the calculation hierarchy results in a compounded uncertainty in the final reference dose and ultimately the MCLG. EPA has not addressed this compounding of uncertainty in any of the technical documents or appendices. This issue is critical, because the cascading uncertainty sheds light on the lack of scientific integrity of the EPA proposed rule.

Table 2. Demonstration of range of BMD values with arbitrary choice of BMR and p(0): Total Cholesterol. Dong et al. (2019) reports BMD=10.5 mg/dL, BMDL=5.6 mg/dl.

Co-variates	(Budtz-Jørgensen & Grandjean, 2018) Method				Liu et al., 2016 Method			
	BMR=0.05		BMR=0.1		p(0)=.1 BMR=0.05		p(0)=.20 BMR=0.05	
	BMD	BMDL	BMD	BMDL	BMD	BMDL	BMD	BMDL
None	55.8	30.8	109.0	60.3	152.4	83.9	504.4	204.4
Age (<20, 21-80) Taking cholesterol drug (yes, no)	150.3	60.9	293.6	118.9	387.8	157.1	341.9	150.1
Age (<20, 21-80) Taking cholesterol drug (yes, no) Ethnicity Gender	102.7	45.4	200.6	88.6	262.0	115.2	341.9	150.1
Age (<20, 21-80) Taking cholesterol drug (yes, no) Ethnicity Gender BMI Category (healthy, obese, overweight, underweight)	103.6	45.0	202.5	87.8	262.0	113.7	345.9	150.1

The following comments (6C – 6F) are specific to USEPA 2023c, but likely also apply to USEPA 2023e.

(6C) EPA made repeated statistical mistakes contrary to accepted practice

In Table E-2 (page E-274) EPA repeats the mistake of excluding important co-variates and acknowledges in Table E-2 that no information is available to ascertain model fit. Again, without

the ability to replicate the Budtz-Jorgensen results and identify if the model from which the BMDL was derived has statistical validity, these results are invalid.

The fundamental statistical mistakes noted above continue with Table E-3 (E-275).

(6D) Inappropriate calculations to reproduce and/or calculate model parameters

(1) Note that EPA in "Selection of Benchmark Response" (following Table E-3) attempts to calculate a pooled variance using Log base 2 of the 25th and 75th percentiles, and uses these percentiles in an attempt to calculate a pooled variance. This calculation is unsupported. EPA acknowledges it does not have the original data, and therefore, it is not mathematically possible calculate a pooled variance. There are many distributions that could result in the same 25th and 75th percentile, but a pooled estimate based on actual data could be very different than what was calculated by EPA. This attempt to overcome lack of actual data is statistically inappropriate. In addition, EPA has no knowledge of how the 25th and 75th percentiles were generated, and cannot replicate these values without the original data set. Also, because the authors make no mention of it, EPA presumably does not know how the original authors treated issues with non-detected values, possibly dropped records, or dealt with sampling issues and weights. Again, EPA cannot use mathematical calculations to overcome the non-available data issue where the results cannot be repeated by the general public or other scientists. The outputs in Table E-4 are unsupported. Even EPA admits there is low confidence in the results, yet EPA continues to use the information. For example, in Section E.71 EPA states "[t]he Agency notes that the estimated models are potentially subject to omitted variable bias from other sources, such as income level, but EPA does not have adequate information to evaluate the impacts of this bias…"

(2) On page E-278, EPA seems to not have the original data for Timmermann et al. (2021) and attempts to back out a regression slope in order to calculate the BMD. This practice is mathematically indefensible, and could easily result in a wrong answer. Also, EPA is required under its own guidelines (USEPA 2003, USEPA 2006) to ensure that, consistent with the data, the original authors did not incorrectly treat the data (i.e., removal of outliers, etc.) prior to using the results for standard setting.

(3) The above inappropriate mathematical and statistical comments also apply to Section E.1.1.4, Modeling Results for Decreased Diphtheria Antibody Concentrations (page E279).

(4) In Section E.1.2.1. EPA again makes unsupported assumptions as to the mean and sigma estimates based on the 25th and 75th percentiles in Chu et al. (2020). EPA needs to obtain the original data, examine the original data using good data practices, and then calculate mean and sigma values. Using the ratio of percentiles reported in a paper is not in line with best statistical practice, and will most likely not represent values obtained using actual data.

(5) See sections E.1.2.2 – E.1.2.7 for continued statistical issues as described above.

(6) In each of the six high confidence studies for which EPA uses to calculate BMD/BMDLs (Sections E.1.2), EPA inappropriately uses the regression coefficients published in the paper, ignoring the fact that the published models incorporate co-variates in their final model. For

instance in Chu et al.(2020) the paper published in Table 2 adjusted regression coefficients for "gestational age, maternal age, maternal occupation, maternal education, family income, parity, and infant sex" (see page 4). When these types of adjustments are made, they are part and parcel of the final and the regression coefficient of interest. For example, b in Table 2 is only statistically valid in the presence of the covariates (also known as confounding variables). In this, and other sections of the report, EPA has repeatedly ignored the full model specification and instead only used the regression coefficient of interest, violating standard statistical principles.

(6E) Single variable regression models can overinflate the relationship to PFAS

Table E-9: EPA states that PFOS is significant in the single-PFAS model. As noted above, when a single variable regression model is applied to a larger data set, the basic tenants of hypothesis testing theory results in significant parameter estimates, simply due to sample size. However, we have showed in our comments that when critical co-variates like gender and age are included in the regression models, the coefficients on PFOA and PFOS are generally non-significant. This is a "signal and noise" problem, with the co-variates easily showing they are much more important to the endpoint (i.e., antibody titer) than PFOS and PFOA blood concentrations.

(6F) EPA's attempts to overcome missing information are inconsistent with accepted scientific practice

EPA's calculation of the "extra risk" in E.1.2.7 is not consistent with sound scientific practice. First, EPA does not know what the true background percentage of PFOS or PFOA is in the US. EPA has not evaluated a national-level exposure of these substances, which would vary tremendously on a national basis. Therefore, EPA's attempts to calculate an "alternative control group" response is not appropriate, and simply represents a statistical calculation that EPA has not defined explicitly. Without an exact understanding of background values (which EPA has not adequately addressed in this rule making), statistical calculations such as those in E.1.2.7 are inconsistent with sound and acceptable practice.

EPA Response: The commenter makes numerous claims regarding the BMD modeling of various critical effects and critical studies. The EPA disagrees with the majority of these claims and responds to the comments in the order they are presented above.

The commenter appears misunderstand how specific values were used in the assessments. As noted in a previous response, the non-significant BMDLs the commenters refer to in their comment 6A were provided for comparison purposes only, which is explicitly stated in Appendix E (USEPA, 2024a; USEPA, 2024b). They were not used to derive candidate reference doses as incorrectly claimed by the commenter. Additionally, none of the reference doses developed by the EPA were used to "set a standard," since the maximum contaminant level goals (MCLGs) were based on the EPA's determination that PFOA and PFOS are *Likely to be Carcinogenic to Humans* according to the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005); the MCLGs for PFOA and PFOS were not derived from non-cancer reference doses. Please also see sections 4.1.2, 4.1.4, and 4.1.5 of the EPA response in this *Response to Comments* document. Additionally, as described above, the original data is often not provided in published

epidemiological studies and study authors provide summary data that are needed for further assessment and calculations, as is the case with the Budtz-Jørgensen and Grandjean (2018). This study was a *medium* confidence study, reflecting the confidence in the study conduct and data quality, including reporting, in the published manuscript. In Appendix E of the draft toxicity assessments, the EPA provided all data and calculations needed to replicate the BMDL derivations (USEPA, 2023b; USEPA, 2023c).

The commenter erroneously claimed that the EPA did not illustrate impact of BMR or p(0) on BMDLs, or that the EPA did not transparently present how a modeling approach was selected. The EPA disagrees with these claims. As stated in the EPA responses to Doc. #1774, SBC-053437, and as is common practice, the EPA cited and referred to EPA guidance (e.g., USEPA, 2012) and used the available study-specific data and characteristics of the critical endpoint inform the choice of BMR, p(0) and modeling approach. The rationale is presented in Section 4 and Appendix E includes numerous sensitivity analyses that illustrate these points, in contrast to the commenter's claims (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b). Please see section 13 of the EPA response in this *Response to Comments* document regarding the economic analyses conducted for this rulemaking.

The commenter made numerous repetitive statements regarding Dong et al. (2019), some of which were discussed in responses in subsection 4.2.2.3.2 below. The commenter erroneously claimed that the Dong (2019) paper did not include key covariates. However, as the EPA clearly states in Section E.1.3.1 in Appendix E (USEPA, 2023b; USEPA, 2023c) "the regression model applies to all adults 20 to 80 years old and was adjusted for age, gender, race, poverty income ratio, BMI, waist circumference, physical activity level, diabetes status, smoking status, and number of alcoholic drinks per day." The commenter did not present sufficient information supporting the analyses illustrated in Table 2 presumed to illustrate range of BMDs with "arbitrary" choices of BMR and p(0) for Dong et al. (2019) for the agency to respond to. The EPA's rationale for BMR selection for TC is presented in Section 4.2 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c). The commenter also did not provide explanation for the "Liu et al. (2016) Method" for the EPA to consider and respond to. The EPA further discusses these topics in the EPA response to comment Doc. #1774, SBC-053230 in section 4.2.2.3 in this *Response to Comments* document.

It is also clear from the Budtz-Jorgensen and Grandjean (2018), as well as the analyses presented in Appendix E that the models for this study controlled for age, gender, and booster type (USEPA, 2024a; USEPA, 2024b). The use of the Faroese study population inherently controls for socioeconomic status and ethnicity based on the characteristics of this population. Every model based on Budtz-Jorgensen and Grandjean (2018) that the EPA presents controls for these covariates and are referred to as "multivariate" models, indicating that more than one variable was accounted for in the modeling approach. The commenter is incorrect in stating that these "statistical mistakes" are repeated throughout the EPA's analyses. Additionally, the EPA describes in Appendix E how Budtz-Jorgensen and Grandjean (2018) fit three model types (i.e., linear, logarithmic, and piecewise) to the data, as well as analyses to determine the statistical validity

(i.e., model fit) (USEPA, 2024a; USEPA, 2024b). The EPA provided the results of these analyses and subsequently used the best fitting models for BMD estimation. For example, in Section E.1.1 in the PFOS Appendix, the EPA wrote, "Budtz-Jørgensen and Grandjean (2018) fit multivariate models of PFOS measured perinatally, against log2-transformed anti-diphtheria antibody concentrations measured at the five-year-old examination controlling for sex and age. Models were evaluated with additional control for PFOA (as log2[PFOA]), and without PFOA. Three model shapes were evaluated by Budtz-Jørgensen and Grandjean (2018) using likelihood ratio tests: a linear model of PFOS, a piecewise-linear model with a knot at the median, and a logarithmic function. The logarithmic functions did not fit better than the piecewise-linear functions Budtz-Jørgensen and Grandjean (2018). Compared to the linear model, the piecewise-linear model did not fit better than the linear model for either the PFOS exposure without adjustment for PFOA using a likelihood ratio test ($p = 0.55$; see Budtz-Jørgensen and Grandjean (2018) Table 3), or for the model that did adjust for PFOA (log2[PFOA]) ($p = 0.84$)," and provides Table E-9 with the corresponding statistical analyses (USEPA, 2023c; USEPA, 2024b). The commenter is incorrect in their assertions that the EPA did not provide this information.

The commenter expresses concern with the EPA's approach to calculating pooled variance using the data provided by the study authors. This calculation is a simple and standard practice, which allows for calculation of mean and standard deviation values based on reported 25th and 75th percentiles and known distribution of the data (Rosner, 2015). The EPA provided all calculations used to estimate pooled standard deviation in Appendix E (USEPA, 2023b; USEPA, 2023c). For example, in Section E.1.1.2.2 EPA states, "[t]he 25th and 75th percentiles of the diphtheria antibody concentrations in the earlier birth cohort at age five years in IU/mL were (0.05, 0.4). Log2-tranforming these values provides the 25th and 75th percentiles in log2(IU/mL) as (−4.32, −1.32). Assuming that these log2-transformed values are similar to the normal distribution, the [interquartile range] IQR is approximately 1.35 SDs, thus SD = IQR/1.35, and the SD of diphtheria antibodies in log2(IU/mL) is (−1.32−(−4.32))/1.35 = 2.22 log2(IU/mL)" (USEPA, 2024a; USEPA, 2024b). The calculations and assumptions the EPA uses to estimate pooled standard deviation follow basic statistical principles (Rosner, 2015) and are supported by publicly available information presented by the study authors. Thus, all computations are replicable.

The commenter misrepresents conclusions the EPA makes regarding individual modeling results and conflates them with the EPA's overall confidence in the immune evidence, antibody response to vaccination endpoint, and confidence in other modeled outputs. In situations where the EPA had relatively low confidence in the POD derived for a particular dataset, which is the case for the example the commenter provided (Table E-4 of the PFOS Appendix, USEPA, 2023c), the EPA does not advance the POD for candidate RfD derivation over PODs derived from other datasets reported by that study (USEPA, 2024c; USEPA, 2024b). The EPA may advance PODs from other studies with modeling results of lower confidence for comparison purposes, as was the case for PODs derived from Timmerman et al. (2021). These conclusions do not equate to the EPA's conclusions regarding the strength of evidence for the endpoint or health outcome, but to different factors specific to that one dataset, such as model fit, statistical associations between the

exposure and response variables, and potential confounding. Conclusions regarding the strength of evidence for each health outcome are presented in Section 3 of the final toxicity assessments (USEPA, 2024d; USEPA, 2024c).

The EPA is unsure where the commenter has identified the quote regarding estimated models. Neither the PFOA nor PFOS Appendices have a Section E.71, and the EPA was unable to identify the language the commenter supposedly quoted in any other section of the assessments or appendices. Therefore, the EPA cannot respond to this comment.

The commenter appears to have a misunderstanding of what data the EPA used from Timmermann et al. (2021) on tetanus or diphtheria antibody responses claiming that the EPA "attempts to back out a regression slope." While the EPA is unclear what the commenter's use of the expression "back out" refers to, the EPA points out that the approach used and described in Appendix E.1 is a simple and standard practice, using a basic mathematical equation which allows for calculation of a regression coefficient from a percent change coefficient reported in a study (USEPA, 2024a; USEPA, 2024b). Also, the EPA had no evidence that the study authors "incorrectly treat[ed] the data." In fact, unlike the commenter who does not provide any substantiating evidence to support this claim, the EPA performed a study quality evaluation of the study that did not result in any concern for data handling or statistical analysis in Timmermann et al., (2021) (see Section 3 of USEPA (2024d; USEPA, 2024c)).

The commenter states that the EPA must obtain the original data from Chu et al. (2020) to calculate mean and standard deviation used in subsequent calculations. The EPA disagrees with this claim. Typically, the original data is not provided in published epidemiological studies and study authors provide summary data that are needed for further assessment and calculations, as is the case with Chu et al. (2020). This study was a *high* confidence study, reflecting the confidence in the study conduct and data quality, including reporting in the published manuscript. The calculation that the commenter takes issue with is a simple and standard practice, which allows for calculation of mean and standard deviation (SD) values based on reported 25^{th} and 75^{th} percentiles and known distribution of the data. Briefly, the EPA used the fact that PFAS exposure follows a log-normal distribution; thus, ln(exposure) follows normal distribution. Since the distribution of exposure is assumed to be normal, the ln(mean) is equivalent to the ln(median), which was available from information provided by the authors. Further, the IQR, the difference between the 75th and 25th percentiles, of a normal distribution is approximately 1.35 SDs (Rosner, 2015). The SD is calculated as: SD = IQR/1.349 = [ln(q3) - ln(q1)]/1.349 = ln(q3/q1)/ 1.349, an equation which is provided in Appendix E (USEPA, 2024a; USEPA, 2024b).

The commenter states that the EPA incorrectly uses regression coefficients published in studies selected for POD derivation because they do not incorporate covariates into these values. The commenter appears to have misinterpreted the methods used in the modeled studies and by the EPA. Given there is no data (i.e., estimate of coefficients and covariance matrix) available for covariates, the EPA assumed the covariates and constant in the original adjusted model were another constant estimated as intercept *b*. The EPA has not ignored the full model specification, since the slopes adjusted for covariates are used in its calculations.

The commenter also stated that the EPA is not transparent in its rationale for including or excluding particular covariates. Additionally, the commenter appears to misinterpret the methods and results of the "single-PFAS model." The EPA disagrees with these claims, as described further below. The EPA clearly states which covariates were adjusted for in each model described. Again, using Budtz-Jørgensen and Grandjean (2018) as an example, the EPA states: "Budtz-Jørgensen and Grandjean (2018) fit multivariate models of PFOS measured at age five years, against log2-transformed anti-tetanus antibody concentrations measured at the seven-year-old examination **controlling for sex, exact age at the seven-year-old examination, and booster type at age five years**" (emphasis added) (USEPA, 2024a; USEPA, 2024b). Additionally, the commenter included Table 1 from Budtz-Jørgensen and Grandjean (2018), which also clearly states that gender, age, and booster type were controlled for. The EPA takes a similar approach for the other health outcomes and endpoints of interest, particularly noting when endpoint-specific covariates were incorporated (e.g., individuals taking cholesterol medication for the total cholesterol endpoint), in multiple locations in the documents, such as in Appendix E, in descriptions of the studies in Section 3 of the final assessment, and in Appendix D presenting detailed information from epidemiologic studies (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b). To further increase transparency, the EPA has subsequently added descriptions of covariates controlled for in each model to the title or footnote of each of the pertinent tables in Appendix E (USEPA, 2024a; USEPA, 2024b).

The commenter misinterprets the meaning of the "single-PFAS model." A "single-PFAS model" is a model which includes only a single PFAS exposure *along with other covariates that are not PFAS exposures*. A multi-PFAS model includes at least two PFAS along with other covariates that are not PFAS exposures. The commentor may be referring to a univariate exposure model which uses a single PFAS exposure to predict antibody concentrations without control of any other covariate. The EPA did not use univariate exposure models in its assessment of PFOA or PFOS (USEPA, 2024d; USEPA, 2024c). To further increase clarity, the EPA has subsequently added a definition of "single-PFAS" and "multi-PFAS" models in the first mention of these terms in Appendix E (USEPA, 2024a; USEPA, 2024b).

The commenter claims the EPA has not defined variables in the statistical analyses used to examine the impact of background exposure and decreased BW incidence in the U.S. This is demonstrably incorrect. The EPA explicitly defined the variables and calculations used to conduct the modeling and sensitivity analyses presented in Appendix E.1.2 of the draft and final toxicity assessments (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b). The EPA walks through each calculation used in the analyses and provides sources for the variables used. Specifically, the EPA cites the CDC Wonder site (https://wonder.cdc.gov/natality.html) as the source for the exact percentage of infants born below the public health definition of LBW and the America's Children and the Environment (ACE) Biomonitoring on Perfluorochemicals (https://www.epa.gov/americaschildrenenvironment/data-tables-biomonitoringperfluorochemicals-pfcs), based on NHANES data, as the source of background PFOA and PFOS serum concentrations in women of childbearing age. The EPA provides sufficient information for an individual to reproduce these analyses and has described

assumptions and decisions made for these analyses in several materials supporting the rulemaking, including this *Response to Comments* document and the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

3M Company (Doc. #1774, SBC-053446)

EPA did not address the inconsistent methods and approaches to BMD calculation in the selected papers and documents used to support the MCLG. This lack of consistency severely limits EPA's ability to reliably and accurately assess potential risk. Note the calculation approach used in (Budtz-Jørgensen & Grandjean, 2018) is completely different than that used by (Dong et al., 2019) (which incorrectly references (Liu et al., 2016)). Different statistical models will, simply based on different mathematics, provide differing results. This uncertainty, and the possible inaccuracy it would cause in the final rule, was not addressed by EPA. For example, EPA has accepted the slope produced by (Dong et al., 2019) when rerunning its BMD calculations yet ignores the fact that the slope is calculated with an incomplete data set, and data weights are not consistent with NHANES guidance. This is clearly a violation of EPA's quality principles and guidance.

EPA Response: This comment is repetitive of similarly incorrect statements provided by the same commenter. Please see the EPA response to comment Doc. #1774, SBC-053296 in section 4.2.2.2.4 in this *Response to Comments* document and the EPA responses to comments in section 4.2.2.2.4 (e.g., Doc. #1774, SBC-053207) for specifics as to why the statements made by the commenter are incorrect.

4.2.2.3.1 Comments Specific to Antibody Response Modeling

3M Company (Doc. #1774, SBC-053447)

EPA inappropriately uses differences in p-values to support selection of single-PFAS models in evaluation of immune responses.

EPA's BMD Technical Guidance states, "the preference in selecting suitable models is to use those that are consistent with the biological processes understood to operate in a particular case and to avoid models that are clearly inconsistent" and provides examples of biological processes include saturable or two-stage processes (EPA 2012 p. 26). EPA recommends use of a "global goodness-of-fit measure, usually a p-value" to "quantify the degree to which the dose-group means that are predicted by the model differ from the actual dose-group mean, relative to how much variation of the dose-group means one might expect." (EPA 2012, p.33). Therefore, the p-value indicates whether or not a model describes the underlying data and is, on its own, not an appropriate statistic for judging model fit in the region of the BMD(L) or making model comparisons. Specifically, EPA states in its BMD Technical Guidance that "P-values cannot be compared from one model to another since they are estimated under the assumption that the different models are correct" (EPA 2012, p. 33), and "Goodness-of-fit statistics are not designed to compare different models – in particular, a higher goodness-of-fit p-value for one model does

not necessarily indicate a better fit over another model with a lower p-value so alternative approaches to selecting a model to use for BMD computation need to be pursued" (EPA 2012 p. 36). Instead, EPA recommends the use of likelihood ratio tests "to evaluate whether the improvement in fit afforded by estimating additional parameters is justified" for models within model families or to the Akaike Information Criterion (AIC) for models within different families (e.g., lognormal versus normal). (EPA 2012, p. 36). Although EPA guidance specifically states that p-values cannot be used to compare different models, EPA here advanced the derivation of a POD for tetanus antibody responses associated with PFOA exposure measured in children at 5 years old based on the model that did not control for PFOS "because this model appeared to fit PFOA data better ($p = 0.02$ vs. 0.07) and there was little uncertainty due to potential confounding in the BMDL" (EPA 2023a, p. E277-278).

Although there are differences in the interpretation of the p-values calculated through traditional BMD approaches and the p-values describing the statistical significance of the models published in the literature, the general principle stands. In fact, as stated by EPA in its BMD Technical Guidance, "when there are other covariates in the models… the idea is the same, but the calculations are more complicated" (EPA 2012, p.33). Due to the complex nature of the multivariate models evaluating epidemiological data, statistics such as the AIC, likelihood ratio test (LRT), residuals in the region of the BMD(L), or adjustedR 2 (for linear models) are more appropriate for determination of comparative fit between models. EPA sets precedence for this type of approach through use of LRT to select use of the linear model instead of the piecewise-linear models reported by Budtz-Jørgensen and Grandjean (2018a) for RfD derivation.

Notably, EPA did not use considerations of comparative model fit (such as the AIC, LRT, or adjusted-R 2) to justify selection of the single-PFAS models reported by Budtz-Jorgensen and Grandjean (2018a). Although EPA justified model selection by noting that there was a small change in BMDL between the single- and multi-PFAS models reported by BudtzJørgensen and Grandjean (2018a) (e.g., the BMDL being 15-19% higher in the multi-PFAS models for 7- and 5-year diphtheria, respectively), this does not preclude the need for consideration of the impact of confounding and co-exposures. Evaluation of the adjustedR 2 for Budtz-Jorgensen and Grandjean's (2018a) models (Budtz-Jørgensen and Grandjean 2018b, 2022a, 2022b) confirms that EPA's comparison of the p-values does not indicate an improved fit of the single-PFAS model. The adjusted-R 2 values of 3.4% and 3.5% for the models with and without adjustment for PFOS, respectively, are comparable. Conversely, the comparison of p-values shows evidence of a potential for confounding by co-exposure with other PFAS. As described in Section 3.3, the fitted models have adjustedR 2 values ranging from 1.0 – 3.7% (Budtz-Jørgensen and Grandjean 2018b, 2022a, 2022b) which indicate that factors other than PFOA or PFOS exposures account for 96-99% of the total variance in antibody response in these models. Therefore, additional caution in model selection and further exploration of the implications of co-exposures to other PFAS on the biological and clinical significance on single-exposure models is necessary.

EPA Response: The commenter stated that the EPA used p-values as a basis for selecting a modeling approach and criticized the EPA's selection of a model that did not account for

exposure to other PFAS. The EPA disagrees with these comments. When possible, the EPA selects more parsimonious models that account for fewer variables as the approach to derive PODs. Accounting for a variable in a multivariable regression model that is not a significant predictor of the response variable reduces the degrees of freedom and effectively dilutes the significance of the other exposure variables that are predictors of the response. In the situation described by the commenter, the EPA stated, "The $BMD_{½\ SD}$ estimate from the multi-PFAS models is 7 percent lower than the $BMD_{½\ SD}$ estimate from the models with just PFOA, and the $BMDL_{½\ SD}$ estimates is 3 percent lower. The change in BMD estimates may, or may not, reflect control for any potential confounding of the regression effect estimates. While it is not clear which PFAS model provided 'better' estimate of the point estimate of the effect of PFOA, the two $BMDL_{½\ SD}$ estimates are comparable (3.35 ng/mL vs. 3.25 ng/mL) and the EPA advanced the derivation based on results that did not controls for PFOS because this model appeared to fit PFOA better (p = 0.02 vs. 0.07) and there was little uncertainty due to potential confounding in the BMDL" (USEPA, 2024d; USEPA, 2024a). These results showed that both models fit the response equally well, though the parameter for PFOA in the single PFAS model did have a lower p-value (p=0.02 vs. p=0.07 for the parameter for PFOA in the multi-PFAS model) and there was little uncertainty associated with the potential for confounding of multiple PFAS in the derived BMDL. Therefore, the EPA selected the BMDL from the more parsimonious model to serve as the basis for the candidate RfD.

The commenter seems to have a fundamental misunderstanding about the meaning and significance for adjusted R^2 values for model comparison. In this modeling scenario, R^2 is not just a measure a model fit as the commenter describes. Indeed, an R^2 statistic reflects the degree of variance in the outcome explained by the covariates in the model. Regardless of how good the model fit is, the R^2 statistic fluctuates with the number of covariates. What is important (and not reflected by the R^2 statistic) is the effect of the exposure on the outcome, adjusted for potential confounders, when modeled appropriately to ensure that the best model fits the data. Also of note, small R^2 values do not necessarily indicate "evidence of a potential for confounding by co-exposure with other PFAS" as the commenter seems to imply.

3M Company (Doc. #1774, SBC-053228)

1. EPA's Selection of Candidate Studies Was Neither Transparent Nor Consistent

The SAB provided specific guidance to EPA that in selecting endpoints for POD development, "[i]nternal inconsistencies in the criteria used for selection of endpoints for POD development should be addressed. It is also important to explain why a specific study of a health endpoint was selected when there are several possible choices." This guidance from the SAB related to all PODs EPA considered. EPA's response was that it presented evidence integration judgments for each health outcome, including the rationale for the selection of a particular study for POD derivation (USEPA 2023c, p. 20-21). Although EPA provided some discussion of evidence integration, it did not explain the choice of study for POD derivation among multiple medium-

confidence studies. The studies selected for POD development had critical deficiencies that should have excluded them from consideration.

First, the evidence base for vaccine response was not consistent. For example, the associations between vaccine response for tetanus or diphtheria with PFOA or PFOS exposures were not consistent either by age nor by vaccine type across several studies (Grandjean et al. 2012; Grandjean et al. 2017a,b; Mogensen et al. 2015; Shih et al. 2021). All of these studies were conducted based on cohorts from the Faroe Islands. Authors noted in 2012 that although negative associations were observed with vaccine antibodies, "the overlapping confidence intervals and the lack of comparative toxicology studies prevent inference in regard to causal attribution" (Grandjean et al. 2012). Similarly in 2017 they noted, "inter-correlations between serum-PFAS concentrations prenatally and at different ages make it difficult to determine accurately the possible age-dependent roles of individual PFASs in regard to immune function outcomes" (Grandjean et al. 2017b). The Agency did not adequately discuss the sporadic findings and uncertainties within the studies examining the Faroe Islands cohorts and to resolve those uncertainties before selecting a candidate study from this group of Faroe Islands cohorts (Butz-Jorgensen and Grandjean 2018).

The alternate candidate study selected by EPA also had critical limitations that should have been identified as part of a proper systematic review. Timmermann et al. (2021) was a cross-sectional analysis of vaccine response in Greenlandic children. Because the exposure and outcome are measured at the same time in a cross-sectional study, the study cannot determine if there is a temporal link between the exposure and the outcome. In addition, the timing of its exposure measurement is unclear compared to vaccination, as vaccination records were not available for nearly half (163/338 children) of the study population, which means the authors estimated the date of vaccination for purposes of evaluating antibody response. Notably, the authors acknowledged that using an estimated date of vaccination likely caused information bias, possibly due to long and varied time intervals since the most recent vaccination. [FN78: Timmermann et al. (2022) is also a poor choice because the children examined in that study had very different chemical exposure levels than American children. They had high levels of mercury and PCB concentrations compared to American children, and PFOS concentrations that were twice as high as American or Faroese children.]

EPA Response: The commenter stated the EPA's selection of critical studies for the antibody response endpoint was not transparent, citing SAB recommendations for providing additional information for selection of outcomes and studies for POD development. The commenter stated the EPA responded to this by providing evidence integration judgements, but the commenter suggested the EPA did not provide justification for decisions on which studies to include for POD derivation and that the EPA selected studies with critical deficiencies for modeling. The commenter raised specific concerns regarding vaccine response studies, suggesting the evidence base for the Faroe Islands population was not consistent across age or vaccine type and had issues such as confounding due to other PFAS and lack of comparable toxicological studies. The commenter also raised concerns about an alternate study, Timmerman

et al. (2021) selected for the EPA's sensitivity analysis, stating that this study should have been excluded because it had a cross-sectional study design, used an estimated date of vaccination for some of the children, and children had different exposure profiles compared to children in the United States. Please see section 4.1.3 of the EPA response in this *Response to Comments* document regarding how the EPA responded to SAB comments.

The EPA disagrees justifications were not provided for selection of studies for POD derivation. The commenter is incorrect in stating the EPA solely provided information regarding critical study selection in the evidence integration sections. The EPA outlined considerations made for study selection for the antibody response endpoint in several sections of the draft toxicity assessments (e.g., Section 4.1.1.2; USEPA, 2023f; USEPA, 2023a). While there were numerous *medium* and *high* confidence studies, the EPA selected studies that met criteria outlined in the Study Selection section, as well as those that met criteria outlined in the Appendices (Section A.1.11.1; USEPA, 2023b; USEPA, 2023c). Reasons for exclusion for other studies were additionally described in Table 4-1 (USEPA, 2023f; USEPA, 2023a). As described previously, the selected candidate studies were the best suited for POD derivation for multiple reasons, such as consideration of potential confounding factors, overall study confidence, study design and analysis, and suitability for modeling. In response to this comment, the EPA has continued to improve the clarity of the rationale for study selection in the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

The commenter claimed that the evidence base for reduced antibody response in children was not consistent, and that the studies selected by the EPA for POD derivation had critical deficiencies. The EPA disagrees that the evidence base for reduced antibody response in children was inconsistent. The commenter provided a limitation described by Grandjean et al. (2012), but does not consider the conclusions provided by the authors of each Faroe Island study. In each case, they conclude that PFAS are associated with reduced antibody response in children, with multiple significant associations reported for PFOA and PFOS (Grandjean et al., 2017; Grandjean et al., 2017; Mogensen et al., 2015; Grandjean et al., 2012,). Across the Faroe Island studies, few non-significant positive associations with tetanus and diphtheria antibody concentrations were observed for PFOA and PFOS, but these estimates were generally imprecise with wide confidence intervals (CIs) (USEPA, 2023f; USEPA, 2023a). In comparison, all other associations were inverse, and significant inverse findings were reported across multiple timepoints. The EPA disagrees that the studies selected for POD derivation had critical deficiencies. Specific to the antibody response endpoint, the two studies selected for modeling, Budtz-Jorgensen and Grandjean (2018) and Timmerman et al. (2021) were both considered *medium* confidence (see Section 3; USEPA, 2024d; USEPA, 2024c), meaning that they did not have critical deficiencies that would render them *uninformative* in accordance with study evaluation considerations outlined in the IRIS Handbook (USEPA, 2022a), the IRIS PFAS Systematic Review Protocol (USEPA, 2021a), or the protocols outlined in Appendix A of the toxicity assessments for PFOA and PFOS (USEPA, 2024a; USEPA, 2024b). Considerations for concerns raised by the commenter for Timmerman et al. (2021) are described later in this response.

Regarding co-exposure to other PFAS, the statement cited from Grandjean et al. (2017b) notes the difficulty in determining potential age-dependent roles of individual PFAS, but it does not question the adverse findings for individual PFAS observed in the study. Notably, Budtz-Jorgensen and Grandjean (2018) performed analyses with and without mutual adjustment for other PFAS and no notable attenuation of the effects were observed for either PFOA or PFOS. The EPA has added additional clarification regarding uncertainties related to potential confounding by co-occurring PFAS in the discussion of uncertainties related to epidemiological studies (USEPA, 2024d; USEPA, 2024c, Sec. 5.1.1). Regarding comparative animal toxicological studies, multiple studies reporting immunotoxic effects in rodent models (e.g., Dewitt et al., 2008; Loveless et al., 2008) were identified and included in the immune synthesis (USEPA, 2024d and USEPA, 2024c, Sec. 3.4.2.2). As noted in the evidence integration summary for immune effects, the immunomodulatory effects observed in these studies were consistent with a diminished antibody response in humans (USEPA, 2024d; USEPA, 2024c, Sec. 3.4.2.4).

The EPA disagrees with the commenter's claims about the Timmerman et al. (2021) study. This study does use a cross-sectional design, however, as PFOA and PFOS have relatively long half-lives in the body, a single measurement is adequately representative of exposure across time. The EPA acknowledged potential information bias in the analysis of all children, specifically those with estimated vaccination dates, reported in Timmerman et al. (2021). This is why analyses examining only those children with known vaccination records was considered the most scientifically accurate and as a result, were the basis for considering Timmerman et al. (2021) for POD derivation. The estimates drawn from Timmerman et al. (2021) used in the sensitivity analysis of tetanus and diphtheria responses in children were from the analysis of children with known vaccination records only. This information was clearly described in Appendix E (section E.1.1.3) of the draft toxicity assessments (USEPA, 2023b; USEPA, 2023c).

3M Company (Doc. #1774, SBC-053448)

Candidate study selection was not transparent.

The studies EPA selected for POD development had critical deficiencies that should have excluded them from consideration. To select endpoints for POD development, the SAB commented, "Internal inconsistencies in the criteria used for selection of endpoints for POD development should be addressed. It is also important to explain why a specific study of a health endpoint was selected when there are several possible choices." EPA's response was that evidence integration judgements were presented for each health outcome, including the rationale for the selection of a particular study for POD derivation (EPA 2023c, p. 20-21). However, EPA did not explain its choice of study for POD derivation among multiple medium-confidence studies.

First, EPA's evidence base for vaccine response was not consistent. For example, the associations between vaccine response for tetanus or diphtheria with PFOA or PFOS exposures in children were not consistent within each of the Faroe Islands studies, neither by age nor by vaccine type

(Grandjean et al. 2012; Grandjean et al. 2017a,b; Mogensen et al. 2015). Authors noted in 2012 that although negative associations were observed with vaccine antibodies, "the overlapping confidence intervals and the lack of comparative toxicology studies prevent inference in regard to causal attribution" (Grandjean et al. 2012). Similarly, in 2017 they noted "inter-correlations between serum-PFAS concentrations prenatally and at different ages make it difficult to determine accurately the possible age-dependent roles of individual PFASs in regard to immune function outcomes" (Grandjean et al. 2017b). Mogensen et al. (2015) also found that the association of PFOA was not statistically significant when adjusted for other PFAS and suggested that results from this study could not attribute effects of vaccine response to any individual compound.

Despite the inconsistency discussed above, EPA summarized the Faroe Island studies as finding "observed associations between higher levels of PFOA or PFOS and lower antibody levels against tetanus and diphtheria in children at birth, 18 months, age 5 years (pre-and post-booster), and at age 7 years, with some being statistically significant", and "There are a few results in the opposite direction for sub-analyses of the Faroe Island cohorts".

The alternate candidate study selected by EPA, Timmermann et al. (2022), is a crosssectional analysis of vaccine response in Greenlandic children that also had critical limitations that should have excluded it from consideration as a candidate study. Due to its cross-sectional design, this study cannot establish temporality between exposure and outcome. In addition, the timing of its exposure measurement is unclear compared to vaccination, as vaccination records were not available for nearly half (163/338 children) of the study population. This means the authors estimated the date of vaccination for purposes of evaluating antibody response. The authors acknowledged that using an estimated date of vaccination likely caused information bias, possibly due to long and varied time intervals since the most recent vaccination.

In the draft toxicity assessments for PFOA and PFOS, EPA noted that Timmermann et al. (2022) did not find consistent evidence of decreased vaccine response within the study population, and there was uncertainty due to "reported results that differed in direction of association based on the covariate set selected. The exposure measurement in these analyses may not have represented an etiologically relevant window." (EPA 2023a, p. 3- 104; EPA 2023b, p. 3-88). Despite no consistent evidence, EPA selected Timmermann et al. (2022) as a candidate study because it was the only study to report the odds of not being protected against diphtheria (based on antibody concentrations of <0.1 IU/ml) (EPA 2023a, p. 3-104; EPA 2023b, p. 3-88). These findings were not statistically significant for PFOA (OR=1.41, 95% CI: 0.91-2.19), but were significant for PFOS (OR=1.14, 1.04-1.26).

Timmermann et al. (2022) is also biased because the children examined in that study had very different chemical exposure levels than other populations. They had high levels of mercury and PCB concentrations compared to American children, and PFOS concentrations that were twice as high as American or Faroese children. Authors admitted that some of these additional compounds were highly correlated, making it difficult to separate their effects on vaccine response from the effects of PFOS/PFOA. Due to the number of associations tested, there was a high risk of finding

significant associations merely by chance. It is unclear why the study was selected by EPA when no significant findings for PFOA were reported. The study design inhibited causal interpretation of the results, and the population was a small population with unique characteristics that preclude any findings from being generalizable to the US population.

In short, both candidate studies contained limitations that EPA's own guidance indicates should have excluded them from consideration as candidate studies. EPA needs to be transparent in its critical appraisal of each study and rationale for the choices of candidate studies.

EPA Response: The commenter incorrectly states that the EPA did not explain its study selection for POD derivation among multiple *medium* confidence studies and that it selected studies for POD derivation that had critical deficiencies. The commenter suggests that the evidence base for vaccine response was not consistent for tetanus or diphtheria by age or vaccine type, and the commenter cites limitations described by each study author regarding their results, which are unrelated to age or vaccine type. The author critiques one critical study (Timmerman et al., 2021) for its design and study population.

The EPA disagrees with comments regarding a lack of rationale for critical study selection and that the selected studies have critical deficiencies. The EPA has explained in a previous response to this commenter (Doc. #1774, SBC-053228), as well as in descriptions provided in Section 4 and Appendix E of the final toxicity assessments (USEPA, 2024d; USEPA, 2024c), rationale for study selection for POD derivation. Rationale included strength of evidence for the specific booster type, confidence in modeling results, study confidence, availability of data appropriate for modeling, overlapping datasets, and others. Further, the EPA reported study evaluation results and noted limitations of each individual study, though no study selected for POD derivation had weaknesses so critical that they resulted in a *low* or *uninformative* confidence designation (USEPA, 2022a; USEPA, 2021a; USEPA, 2024a; USEPA, 2024b). Further, when considered together, as is the goal of the evidence integration process, the overall database showed consistent responses across multiple boosters and study populations (see Section 3, USEPA (2024a) and USEPA (2024b)). Consistency among age groups is not necessarily expected for this endpoint. The weaknesses of individual studies are overcome with support across the database, as is the case for epidemiological and toxicological studies indicating associations between PFOA or PFOS and immunosuppression.

The commenter noted limitations reported by Grandjean et al. (2012) as "overlapping confidence intervals" and a "lack of comparative toxicology studies." Similarly, the commenter cites another limitation described by a Faroe Islands study author (Mogensen et al., 2015), noting lack of statistical significance after adjustment for other PFAS. Regarding lack of comparative toxicological studies, multiple toxicological studies (Dewitt et al., 2008; Loveless et al., 2008; Zhong et al., 2016; Peden-Adams et al., 2008; Dong et al., 2009) observed decreases in globulin and immunoglobulin levels and other responses indicating immunosuppression after exposure to PFOA and PFOS, consistent with decreased antibody response observed in humans (USEPA, 2024d; USEPA, 2024c). Furthermore, mechanistic evidence (NTP, 2016) published after the Grandjean et al. (2012) study provided evidence of T-cell-dependent and T-cell-independent

responses being reduced in mice treated with PFOA, suggesting a possible explanation for decreased antibody response in humans (USEPA, 2024a). Regarding overlapping CIs and statistical significance after adjustment with other PFAS, the IRIS Handbook states that "consideration of the consistency in patters of results does not require that all findings are statistically significant" (USEPA 2022a, p. 6–19). Consistency of direction and magnitude of observed effects across the immune database were considered while drawing conclusions about vaccine response in children.

The agency had lower confidence (i.e., identified greater uncertainties) in PODs derived from Timmerman et al. (2021) compared to the selected PODs derived from Budtz-Jørgensen and Grandjean (2018) for multiple reasons, including some that the commenter quotes from Appendix E, as well as in Section 4 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b). The commenter did not provide new rationale that the EPA had not already considered when selecting the health outcome-specific RfD for immune effects. However, the EPA disagrees with the commenter's assertion that the EPA selected Timmerman et al. (2021) as a critical study because "it was the only study to report the odds of not being protected against diphtheria." The SAB recommended the EPA consider different populations in selecting studies for POD derivation (USEPA, 2022b, p. 35). Timmerman et al., (2021) was chosen for comparison purposes as it represented another population—children from Greenland—compared to studies conducted in the Faroe Islands. As the EPA noted in previous responses (e.g., Doc. #1774, SBC-045661), a cross-sectional study design does not preclude a study from quantitative consideration. Overall, the EPA relied on the most reliable modeling results and best-conducted studies available to serve as the basis for the health outcome-specific RfD for immune effects (Budtz-Jørgensen and Grandjean, 2018).

3M Company (Doc. #1774, SBC-053289)

(2C) EPA's removal of important modeling co-variates is not accepted practice and is inconsistent with study authors' conclusions.

EPA's improper analyses and lack of justification for alterations of previously published models lacks statistical rigor, are problematic, and leads to incorrect conclusions. An important modeling approach for assessing population phenotypes that aid in the assessment of representative models, is to include at least some basic population information like ethnicity, age, gender, socioeconomic status, and other components in the model. Here, EPA's failure to adjust BMD calculations for key co-variates results in incorrect BMD model generation which led to incorrect BMDL values.

In fact, the Budtz-Jørgensen & Grandjean (2018) study reveals, both in the SAS output and as clearly stated in the original paper (at 7), when co-variates like gender, age, and type of booster are included in the model, the relationship of PFOS or PFOA blood concentrations are shown to have a non-significant relationship with antibody titer changes (see Table 1, below reproduced from Table 1 of Budtz-Jørgensen & Grandjean, 2022). We provide other examples where models

are developed without inclusion of important statistically significant covariates arises later in the comments. For example, we will demonstrate that the PFOA and PFOS blood concentration relationships to selected response variables are very weak to non-existent when using US nationally representative data such as NHANES.

Table 1. PFOS Model Non-Adjusted Copied from Output Sent to EPA

PFOS Model Non-Adjusted	
Variable	Pr > t
Intercept	0.510
PFOS Parameter	*0.120*
sex	0.006
Age at 7 years	0.388
Booster type at age 5	0.860
From Table 1 of (Budtz-Jørgensen & Grandjean, 2022)	

In addition, EPA has not explained when or why co-variates are either included or excluded from the statistical models used by EPA to support the MCLG. This lack of scientific rigor in model development is clearly a violation of good statistical practices (Harrell 2016). When key population metrics are included in the model, these metrics dominate any relationship between the response variable and the model parameters. In such models, the parameter associated with either PFOA or PFOS is generally statistically insignificant.

EPA Response: The commenter incorrectly stated the EPA failed to adjust for covariates, including ethnicity, age, gender, and socioeconomic status (SES) in its modeling approach and BMD calculations and even "removed" covariates from analyses. The commenter particularly criticizes the results from Budtz-Jørgensen and Grandjean (2018), claiming that once covariates are incorporated into the modeling, associations between PFOA or PFOS and antibody response are no longer statistically significant. The EPA disagrees with all of these claims, as described further below.

First, the EPA did adjust for important covariates in its modeling. For example, results from Budtz-Jørgensen and Grandjean (2018), were adjusted for age, gender, and booster type. Ethnicity and socioeconomic status were not adjusted for given the nature of the Faroese population (i.e., the Faroese are a relatively homogenous population in terms of these two characteristics). The EPA also notes this statement from the SAB PFAS Review Panel on SES: "Assuming that any and all components of SES will always confound associations with PFAS is not supportable" (USEPA, 2022b). As suggested by the SAB, the EPA takes a case-by-case approach to determine which covariates should be considered in each analysis. Please also see the EPA response to comment Doc. #1774, SBC-053296 in section 4.2.2.2.4 in this *Response to Comments* document.

Second, regarding the results from Budtz-Jørgensen and Grandjean (2018), the table of results provided by the commentor accurately shows the PFOS regression output, which the EPA also

reports in Appendix E as p=0.12 (USEPA, 2024a; USEPA, 2024b). Further, the EPA clearly states, "PFOS is a non-significant predictor in the single-PFAS model (β = −0.0274; p = 0.12)." The commenter is not providing new information that the EPA did not already describe in its supporting documents. The EPA also provided rationale for its determination to model this data, noting, "…these data can be used to estimate a BMDL for completeness and to **allow comparisons across PFAS**" (emphasis added). The EPA did not bring BMDLs based on this data forward for RfD derivation and used them for comparison purposes only.

Finally, the commenter incorrectly states that regression coefficients were generally non-significant once covariates were incorporated into the models. Specifically for results from Budtz- Jørgensen and Grandjean (2018), all four models of PFOA (two for tetanus and two for diphtheria) were significant. Out of eight combinations (i.e., antibody type, sample timing, and single-PFAS vs multi-PFAS models) across PFOS and PFOA, six results were statistically significant. All of this information was clearly and transparently provided at the time of rule proposal in the appendices to the draft toxicity assessments (USEPA, 2023b; USEPA, 2023c) and contributed to the overall weight of evidence supporting the quantitative consideration of this endpoint. The EPA did not "remove covariates" but, as described in the EPA response to comment Doc. #1774, SBC-053447 in section 4.2.2.3.1 in this *Response to Comments* document, when possible, as was the case here, the EPA selects more parsimonious models that account for fewer variables as the approach to derive PODs.

3M Company (Doc. #1774, SBC-053449)

EPA also fails to consider potential complications from the use of simple univariate linear assumptions for estimation of regression coefficients from multivariate analyses. For example, "For the immune studies, where a clinically defined adverse level is not well defined, EPA used multivariate models provided in the studies and determined a BMR according to EPA guidance to calculate BMDs and BMDLs" (EPA 2023a, P. 2-16). When EPA computed the "Regression coefficients (β) and their standard errors (SE)… from the published BMDs and BMDL based on a BMR of 5% decrease in the antibody concentration in Table 1 of Budtz-Jørgensen and Grandjean (2018, 5083631)" (EPA 2023a, p. E-269; EPA 2023b, p. E-1), it may not have appropriately factored in the complexities of adjustments for other confounding or explanatory variables (including age, sex, or adjustment for other PFAS) and therefore may have uncertainties in the computed regression coefficients. Based on the statistical outputs provided in Budtz-Jørgensen and Grandjean (2018b, 2022a, 2022b) documentation, the regression coefficient for sex is up to 3-fold larger than the coefficient for exposure in the model based on PFOA exposure and tetanus antibody concentrations at age 7. Findings like these highlight the potential impact of confounding factors and indicate potential areas of uncertainty in simplistic extrapolations from reported BMD(L)s.

EPA Response: The commenter appears to misunderstand the modeling approach. Please see the EPA response to this commenter (Doc. #1774, SBC-053289) above.

3M Company (Doc. #1774, SBC-053450)

With respect to immune response outcomes, EPA argues that the statement from WHO (2018) that "a 'protective antibody concentration' may not be considered a guarantee of immunity under all circumstances" indicates an absence of a clear definition of an adverse effect. Regardless, "As a check, EPA evaluated how much extra risk would have been associated with a BMR set at a cutoff value of 0.1 IU/mL" (EPA 2023b, E-273). However, EPA does not describe the methods for derivation of a hybrid "extra risk" BMR with a cutoff of 0.1 IU/mL, nor does it describe the resulting BMD(L)s. Based on the limited reporting, it does not seem that EPA re-calculated a BMD(L)s based on the assumption of clinical protection at 0.1 IU/mL and, instead, used "the observed distribution of tetanus antibodies" to calculate the extra risk of values below the cutoff of 0.1 IU/mL. Additional transparency is needed in order to understand 1) the methods used and 2) the impact of using alternative BMRs based on clinical cut-points on BMD(L) derivation.

EPA Response: The commenter misunderstands the modeling approach described in the draft toxicity assessments for PFOA and PFOS (USEPA, 2023b; USEPA, 2023c). The commenter incorrectly claimed that the EPA did not adequately describe the methods for derivation of a hybrid "extra risk" BMR with a cutoff of 0.1 IU/mL and that the agency did not describe the resulting BMD(L)s. The extra risk analysis was a sensitivity analysis, the methods for which are described in agency guidance (USEPA, 2012), not an analysis that was meant to produce a BMDL. The extra risk check was meant for illustrative purposes that the use of ½ SD is a reasonable estimate of a 5 percent extra risk. However, the analysis does indicate that even if the agency had selected the hybrid approach using a cutoff of 0.1 IU/mL, there would likely be minimal impact on the BMDLs. The EPA presents rationale for why the hybrid approach was not used for this endpoint in Appendix E and Section 4 (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

Raptor Pharm & Tox, Ltd (Doc. #1644, SBC-052845)

Budtz-Jorgensen and Grandjean 2018

This study did not demonstrate an adverse human health outcome. I have discussed issues with this study in detail elsewhere (https://toxictruthblog.com/epa-pfoa-and-pfos-health-advisories-violateguidelines-and-sdwa/). Briefly, if one looks at Figure 1, it is apparent that the Budtz-Jorgensen and Grandjean model only goes down to a diphtheria antibody concentration of 0.444 IU/mL – that's 44x larger than the basic immunity threshold of 0.01 IU/mL. What this means is that the Budtz-Jorgensen and Grandjean model is incapable of establishing that diphtheria antibody concentrations reach the level where adverse human health outcomes occur.

In addition, Budtz-Jorgensen and Grandjean is simply correlative. It is not causal. One cannot use this study to state that "but for PFOS/PFOA, the diphtheria antibody levels would be normal." There is no way for this study to make such a claim as it is not possible to test the counterfactual condition required to make the causal argument.

In addition, the BMDL identified in Budtz-Jorgensen and Grandjean violates the US EPA's Benchmark Dose Technical Guidance. In US EPA's Draft Approaches to the Derivation of an MCLG for PFOS in Drinking Water, US EPA echoes what Budtz-Jorgensen and Granjean state as a justification for their improper use of a 5% BMR when US EPA states: "for a developmental effect, a BMR of 5% is recommended. Given the range of health outcomes includes fatality and the effect on children, a BMR of 5% is a reasonable and appropriate choice." That is in violation of the Benchmark Dose Technical Guidance.

EPA misapplied the BMD guidance by confusing the data they actually have in Budtz-Jorgensen and Grandjean, which is continuous, for quantal data, thereby misapplying the quantal guidance to the continuous data.

Or more precisely, Budtz-Jorgensen and Grandjean are misapplying The Benchmark Dose Technical Guidance, and EPA is going along for the ride, but chooses to justify the 5% benchmark response (BMR) in a slightly different way.

What EPA and Budtz-Jorgensen and Grandjean did was to read the wrong part of the Benchmark Dose Technical Guidance; specifically they both are referencing the (dichotomous) data section "…most reproductive and developmental studies with nested study designs easily support a BMR of 5%. Similarly, a BMR of 1% has typically been used for quantal human data from epidemiology studies." BudtzJorgensen and Grandjean reasoned that a 5% BMR was more appropriate because it was the "lower BMR", which defies logic as a 1% BMR is also mentioned; however, more importantly EPA improperly concluded that a BMR of 5% is appropriate "[g]iven the range of health outcomes includes fatality and the effect on children…"

However, Budtz-Jorgensen and Grandjean data are continuous. That means EPA must apply the continuous data guidance, not the quantal data guidance. The continuous data guidance begins in the very next section and paragraph of the Benchmark Dose Technical Guidance. Therefore, as the data in Budtz-Jorgensen and Grandjean is continuous data, and not quantal data, EPA has misapplied the BMD Guidance, and has used an inappropriate BMR.

These points taken together demonstrate that EPA/OW has grossly misapplied the BMD process and has made a significant error.

What EPA should have done is clearly stated in the Benchmark Dose Technical Guidance because they have continuous data and a consensus basic immunity threshold for diphtheria antibodies (page 22):

The ideal is to have a biological basis for the BMR for continuous data, e.g., a consensus scientific definition of what minimal level of change in a continuous endpoint is biologically significant.

US EPA, Benchmark Dose Technical Guidance, page 22

This means that EPA, and not Budtz-Jorgensen and Grandjean, must use the consensus, clinically validated antibody threshold, established by the CDC, FDA, and the WHO in their benchmark dose analysis. That level is 0.01 IU/mL.

Bottom Line: EPA should have used the basic immunity threshold of 0.01 IU/mL as the BMR. Therefore, EPA erred when it stated that a 5% BMR is reasonable and appropriate.

EPA Response: Regarding the adversity of the antibody response critical effect, please see section 4.2.2 of the EPA response in this *Response to Comments* document. Additionally, the commenter stated that "the Budtz-Jorgensen and Grandjean model is incapable of establishing that diphtheria antibody concentrations reach the level where adverse human health outcomes occur." The EPA disagrees with this statement and the rationale provided by the commenter as support. Although the study did not demonstrate clinical cases of disease for the pathogens examined in Budtz-Jorgensen and Grandjean (2018), the EPA and the SAB agreed clinical manifestation of the disease was not necessary to demonstrate an adverse, immunotoxic effect:

"The SAB's PFAS review panel noted that reduction in the level of antibodies produced in response to a vaccine represents a failure of the immune system to respond to a challenge and is considered an adverse immunological health outcome {USEPA, 2022, 10476098}. This is in line with a review by Selgrade (2007, 736210) who suggested that specific immunotoxic effects observed in children may be broadly indicative of developmental immunosuppression impacting these children's ability to protect against a range of immune hazards—which has the potential to be a more adverse effect that just a single immunotoxic effect" (USEPA, 2023f; USEPA, 2023a, Sec. 4.1.1.2; see also USEPA (2022b))).

The EPA also notes that this one study was not the sole basis of the EPA's determination that the *evidence indicates* that there is likely an association between PFOA and PFOS and adverse immune effects in humans. For further discussion on the EPA's weight of evidence approach and systematic review of the literature, please see section 4.1.1 of the EPA response in this *Response to Comments* document, and for discussion specific to the antibody response effect, please see the EPA response to comment Doc. #1774, SBC-053430 in section 4.2.1.4 in this *Response to Comments* document.

The commenter incorrectly stated that the EPA used a BMR of 5 percent to estimate PODs for immune endpoints. As described in Appendix E.1 (USEPA, 2023b; USEPA, 2023c), the "EPA reevaluated the approach chosen by Budtz-Jørgensen and Grandjean (2018, 5083631) and determined that a different approach should be used to be consistent with EPA guidance {U.S. EPA, 2012, 1239433}, which recommends the use of a 1 or ½ SD change in cases where there is no accepted definition of an adverse level of change or clinical cut-off for the health outcome." The EPA ultimately selected a BMR of ½ SD change, which is described in Section 4.2 and Appendix E of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

The commenter also stated that the EPA should have used the "clinically validated antibody threshold" of 0.01 IU/mL as the BMR for the antibody response endpoint modeling. As

discussed in Appendix E and Section 4.2 of the toxicity assessments, the EPA disagrees with this approach (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b). More specifically, the EPA stated in the draft assessments (USEPA, 2023b; USEPA, 2023c) "[t]he amount of circulating antitoxin needed to ensure complete immunity against tetanus is not known for certain. Establishment of a fixed level of tetanus antitoxin does not take into consideration variable conditions of production and adsorption of tetanus toxin in the anaerobic area of a wound or a necrotic umbilical stump. A given serum level could be overwhelmed by a sufficiently large dose of toxin. Therefore, there is no absolute protective level of antitoxin and protection results when there is sufficient toxin-neutralizing antibody in relation to the toxin load (Passen and Andersen, 1986)."

Connecticut Department of Public Health (Doc. #1745, SBC-045208)

EPA requests comment on the derivation of the proposed MCLG for PFOA. EPA is also seeking comment on its assessment of the noncancer effects associated with exposure to PFOA and the toxicity values described in the support document on the proposed MCLG for PFOA.

The noncancer RfD of PFOA is based on the reduced antibody responses (anti-tetanus and anti-diphtheria) reported by Budtz-Jørgensen and Grandjean (2018). CT DPH recommends EPA to add more explanation on whether this health endpoint is significant in public health (i.e. how it may be related to the actual prevalence of tetanus and diphtheria). The clinical relevance is unclear for a 5% decrease in antibody responses to tetanus and diphtheria vaccines, a fact that EPA acknowledged in its draft proposed MCLGs for PFOA and PFOS (EPA 2021; Appendix B, Section B.1.1). In general, the lack of antibody responses to vaccinations does not equate to having an increased susceptibility to clinically significant disease; it is unknown whether persons that fail to mount sufficient antibody response (≤ 0.1 IU/mL) are at higher risk to acquire infections or develop disease (Weidermann et al. 2016). Moreover, there is no evidence that a reduction in serum antibody levels has any long-term effect (lifetime) on a person's health.

However, there is good evidence that the intensity of the humoral response to trigger the production of specific antibodies in response to a given stimulation is highly variable (Bil et al 2023) and influenced by a variety of factors that include age, gender, and genetics (Scepanovic et al 2018; Tsang et al. 2014; Ovysyannikova et al 2004). Such high variability in response to vaccinations was listed as one of the main reasons that researchers were unable to derive internal relative potency factors (RFPs) for the immunosuppressive effects of PFAS based on NHANES data in 12-19 year olds. A better understanding of the natural variation in human response to vaccinations is needed to support the use of immunomodulation associated with PFAS exposure as a point of departure for human risk assessment (Antoniuo et al 2022). CT DPH recommends EPA provide more explanation of the mechanisms by which PFAS alters the immune status, a necessary step to establish the validity of markers for predicting disease and the degree of their predictability.

CT DPH also encourages EPA to add more discussion on whether there is enough evidence that the findings in the studied population (Faroese children) is also representative of the general US population. Without such information, derivation of PFOA RfD based on this study may not be well supported to reflect the human health effects of PFOA exposure in the US through drinking water. The EPA risk analyses, based on geometric mean (g.m.) serum PFOA and PFOS levels in Faroese children at age 5 that are 3-fold (PFOA) to 4-fold (PFOS) higher than levels measured in the total U.S. population (NHANES 2017-2018), and the difference is likely greater for PFOS (up to 5-fold) if comparative data were available for U.S. children; NHANES (2013-14) data showed children aged 3 to 5 years had 1.5-fold lower PFOS levels than the those for the total U.S. population. Moreover, the immune effects measured in the Faroese children are likely impacted by their higher concentrations (compared to U.S. general population) of serum methylmercury (~10-fold higher) and PCBs. Both have been linked to developmental immunotoxicity in studies of experimental animals (methylmercury; Tonk et al. 2010) and in studies of this Faroese cohort: higher serum PCBs reduced antibody responses to diphtheria and tetanus vaccinations (Heilmann and Grandjean et. al. 2006; Heilmann and Budtz-Jorgensen et al. 2010), prenatal concentrations of mercury and PCBs were associated with lower autoantibodies (Osuna and Grandjean et al. (2014), while children's serum levels of PCBs and methylmercury at age 7 were associated with both an increase and decreased risk of allergic disease (Grandjean et al. 2010). Levels of serum PCBs (as well as DDE) have also been associated with reduced antibody response to infant tuberculosis vaccinations in Slovakian populations (Jusko et al 2016).

More recently, EPA IRIS (2023) derived an RfD for PFDA (0.004 ng/mg-d) that is 7.5-fold more conservative than the RfD (0.03) for the PFOA proposed MCLG, based on analyses of data from the same Faroese cohort that used the same endpoint (reduced Ab response to diphtheria and tetanus) and same BMD approach (0.5% SD BMR) as was used to derive the RfD for proposed MCLG for PFOA. The more conservative RfD for PFDA suggests that PFDA has a much greater impact on antibody response than PFOA and PFOS, and illustrates the difficulties of trying the disentangle the immune effects of individual PFAS from one another, notwithstanding the need to evaluate the impact of other immunotoxicants (methylmercury and PCBs) on antibody response in the Faroese population (there is no mention of methylmercury or PCBs in the proposed MCLGs for PFOA and PFOS).

The above listed points only scratch the surface of the complex issues and uncertainties surrounding the use of human data, and specifically antibody responses to vaccinations, as a critical endpoint in the risk assessment of PFOA and PFOS. Therefore, CT DPH recommends that EPA consider the use of other critical endpoints in its non-cancer risk assessment for PFOA and PFOS.

CT DPH also requests that EPA provide a more in-depth explanation of why it chose to use a different BMD model (linear) that resulted in chronic RfDs for PFOA and PFOS that are 20- and 25-fold higher than the respective RfDs derived using the BMD (piecewise linear) model

selected in the draft MCLGs for PFOA and PFOS because "the piecewise model tended to show slightly better fit values due to greater flexibility" (EPA 822D21001; December 2021).

EPA Response: The commenter appears to have been referencing earlier draft versions of the toxicity assessments (USEPA, 2021b; USEPA, 2021c) submitted by the EPA to the SAB for peer review, rather than the draft toxicity assessments that were published at the time of rule proposal (USEPA, 2023f; USEPA, 2023a) that were updated based on the feedback from the SAB (USEPA, 2022b). Therefore, many of the commenter's requests and concerns are no longer relevant. For example, the commenter recommended that the EPA "add more explanation on whether this health endpoint is significant in public health," which was available in Section 4.1 of the 2023 draft assessments (USEPA, 2023f; USEPA, 2023a). The commenter also requested clarification on the clinical relevance of a BMR of 5 percent for the antibody response endpoint, which was updated to a BMR of 0.5 SD in the 2023 draft assessments. Additionally, the EPA provided discussion on potential mechanisms of immune toxicity in Section 3.4.2.3 of the draft toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a) and the commenter quoted text from the 2021 draft versions of the PFOA and PFOS toxicity assessments that was no longer presented in the 2023 public comment drafts. The commenter requested the EPA consider the use of other critical endpoints in the agency's non-cancer risk assessment. Again, the agency did do this in the draft assessments published at the time of rule proposal (USEPA, 2023f; USEPA, 2023a). More specifically, the EPA selected co-critical effects of reduced antibody response to vaccination in children, increased serum total cholesterol in adults, and decreased infant BWT as the basis of the overall RfD for PFOA and co-critical effects of increased serum total cholesterol in adults and decreased infant BWT as the basis of the overall RfD for PFOS. For PFOS, antibody response to vaccination is no longer considered a co-critical effect, though the EPA presented a candidate RfD for this endpoint which serves as the basis for the PFOS immune health outcome-specific RfD. The EPA responds to portions of this comment that are relevant to the 2023 draft toxicity assessments below.

Regarding the adversity of the antibody response endpoint and comparisons between the Faroese and U.S. populations, please see section 4.2.2 of the EPA response in this *Response to Comments* document. Regarding the EPA draft PFDA assessment, a BMR of 0.5 SD (not 0.5 percent SD) was used for BMDL estimation, which is consistent with the EPA's BMR selection in the draft and final PFOA and PFOS toxicity assessments (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). The PFDA assessment also compared BMDLs determined based on regression coefficients from models with and without additional adjustment for PFOA and PFOS, and they were very similar (0.411 *vs.* 0.497 ng/mL in serum), indicating that potential confounding by PFOA and PFOS may not have a significant impact on that exposure-response relationship. The EPA disagrees that there is no mention of methylmercury or PCBs in the toxicity assessments for PFOA and PFOS. The EPA notes in Appendix D when studies controlled for methylmercury or PCBs, as well as in the study quality evaluations available in HAWC and Section 3 of the toxicity assessments (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b). Again, the commenter may have been referring to the earlier versions of these assessments published in 2021 (USEPA, 2021b; USEPA, 2021c).

4.2.2.3.2 Comments Specific to Total Cholesterol (TC) Modeling

3M Company (Doc. #1774, SBC-053293)

4. NHANES cholesterol values changed significantly due to non-PFAS factors

NHANES determined that a change in assay methods was most likely responsible for changes in HDL cholesterol values in the NHANES cycles from 1999-2008 (Source: National Health and Nutrition Examination Survey, 1999-2000 Data Documentation, Codebook, and Frequencies Cholesterol L (Lab13) https://wwwn.cdc.gov/Nchs/Nhanes/1999- 2000/LAB13.htm). NHANES developed a formula to correct HDL values and re-posted the corrected data. It is very rare that papers document when data extracts were downloaded but it is not uncommon for papers to take more than two years from publication to data analysis and papers published with data prior to corrections will have inaccurate findings. The following table shows the original dates of data published for cholesterol as well as prescription drugs.

NHANES Cycle	Prescription Drugs		TC & HDL		LDL	
	First Published	Last Revised	First Published	Last Revised	First Published	Last Revised
1999-2000	-	-	Jun-02	Apr-10	Jun-02	Mar-07
2001-2002	-	-	Sep-04	Apr-10	Jun-05	Mar-07
2003-2004	Aug-07	Jun-09	Jun-06	Apr-10	Sep-06	May-08
2005-2006	Sep-08	Jun-09	Nov-07	Apr-10	Mar-08	
2007-2008	Apr-10		Sep-09	Feb-10	May-10	Sep-10
2009-2010	May-12		Sep-11		Dec-11	
2011-2012	Jul-14		Sep-13		Jan-14	
2013-2014	Dec-16		Oct-15	Mar-16	Mar-16	
2015-2016	Jan-19		Sep-17		Jan-19	
2017-2018	Mar-20		Feb-20		Dec-20	Mar-21
2017- Pre 2020	Sep-21		Aug-21		Oct-21	

Again, any and all analyses that EPA is relying on that included NHANES data must use the most accurate datasets supplied by NHANES.

EPA Response: The commenter suggested that NHANES HDL cholesterol values were corrected which resulted in the EPA relying on studies using inaccurate data in their analyses. The EPA disagrees that studies included in dose-response analyses utilizing NHANES data were inaccurate. Dong et al. (2019) was the only NHANES study the EPA modeled for total cholesterol. The study was published in 2019, and by the commenter's own estimation of two years between data analysis and publication, Dong et al. (2019) would have had access to updated NHANES data, which, according to commenter's table, were primarily adjusted in 2010 to account for the change in assay methods. Further, the EPA re-analyzed the data using the same model from Dong et al. (2019) with updated NHANES data from 2022 (USEPA, 2023c; USEPA,

2023b, Sec. E.1.3.1). Considering the timing of the publication of Dong et al. (2019) and the EPA's re-analysis presented in the draft toxicity assessments, NHANES updates over a decade prior would not be a concern. HDL cholesterol was not a modeled endpoint, nor was it considered a supporting factor for cardiovascular effects of PFOA or PFOS (USEPA, 2024d; USEPA, 2024b, Sec. 3.4.3.4.1).

3M Company (Doc. #1774, SBC-053295)

5. Dong et al., 2019, a key study upon which EPA relies, has serious methodological issues that render it unreliable.

EPA repeatedly cites Dong et al. (2019) in estimating Point of Departure (POD), reference dose (RfD), and benchmark dose (BMD) (USEPA 2023b, 2023d). The importance of this paper in EPA's analysis can be seen in particular on:

· Page F-10 of USEPA 2023b states "Although the datasets and models were not exactly the same in all NHANES-based studies, to avoid estimate dependency issues due to overlapping populations in the meta-analysis, EPA also performed a sensitivity analysis including only the data from the study covering the broadest range of NHANES cycles (2003–2014) (Dong et al.,2019)."

· Page K-4 of USEPA 2023b states "The use of single study-based TC effect estimates, rather than EPA meta-analysis-based effect estimates. To this end, EPA used estimates from a large NHANES study (Dong et al., 2019) …"

· Page E-298 of USEPA 2023c states that EPA re-analyzed the data using the regression models from the Dong et al., 2019 study, together with updated NHANES data, applied to a modified hybrid model to develop BMD and BMDL estimates for various time periods and assumptions.

Methodological issues with Dong et al.(2019) that seriously impact the veracity of the statistical associations found and alter the fundamental representational aspects of NHANES data include:

1. Dong et al. (2019) did not analyze the full NHANES dataset but rather excluded certain cholesterol and PFAS values. On page 463 the authors state, "to ensure no influential points heavily impact on the analysis results, the outliers for PFASs and cholesterol (data points more than 1.5 interquartile ranges (IQRs) below the first quartile or above the third quartile) were excluded."

2. Not only did the authors exclude portions of the original data for outliers, they also excluded based on age on page 464. The authors state, "The regression analysis was also conducted for adults [20-80 years] since most correlations observed for adolescents were insignificant." Data should only be excluded when they are known to be incorrect, due to laboratory measurement errors, etc. When data exclusion changes the results of the study or misrepresents the study, exclusion of the data is improper (Resnick 2000). EPA has not justified data exclusions by any of

the outside authors, and EPA has not internally rigorously evaluated data treatment nor established good data treatment guidelines that are consistent with DQOs.

3. The final regression models for BMD calculations published by the authors did not adjust for gender nor age despite the fact that these co-variates were found to be significant by their own analyses.

4. As recognized by EPA, Dong et al. (2019) did not explicitly state that the models generated used the appropriate NHANES weighting.

5. Dong et al. (2019) used custom code within a statistical software package (Matlab) to conduct a hybrid BMD calculation rather than using EPA approved BMD modelling software (e.g. BMDS (USEPA 2022))

Given these serious statistical and methodological issues, rating the Dong et al. (2019) study as a medium quality study, as EPA did here, is inconsistent with EPA statements on how it judged the merits of specific studies for the purpose of assigning a quality score. Additionally, given that the exclusion done by the authors removes the national representative nature of the NHANES dataset and introduces strong bias into the analysis, it is inconsistent with sound science and EPA's own guidance to use it as a basis for calculating BMDs.

Despite these significant issues with Dong et al., (2019) EPA retained the slope estimates and used these flawed estimates to calculate BMD and BMDL (see page E-298 of U.S, 2023c "where m is the slope, β, (from the Dong regression model) and b is the intercept."). It is not proper statistical practice to realize that a previous analysis used flawed methodologies and verify that with your own analyses as EPA did here, only to go ahead and use the incorrect values.

EPA has not followed its own QC guidelines when using findings from outside sources. EPA has not questioned many of the selected author's findings or taken steps to replicate them, nor has EPA reviewed the original author's poor data treatment. Given the deviation from sound practice and EPA guidance with respect to EPA's treatment of Dong et al. (2019), it is likely this lack of quality control and poor statistical practice has carried over to other data and statistical modeling activities throughout the technical portion of the Proposed NPDWR.

EPA Response: The commenter stated that the *medium* confidence rating for Dong et al. (2019), as well as its use in deriving PODs and candidate RfDs, is inconsistent with the EPA's guidance. Specific issues with this paper raised by the commenter included: the exclusion of outlier values of PFAS and cholesterol; the exclusion of NHANES participants under age 20; a lack of adjustment for age and gender in the regression models for BMD modeling; uncertainty regarding how the NHANES data were weighted (please see the EPA response to comment Doc. #1774, SBC-053293 in section 4.2.2.3.2 in this *Response to Comments* document); and how the EPA conducted hybrid BMD modeling using code the commenter characterized as not developed using "EPA approved BMD modelling software." The EPA disagrees with these statements.

First, the EPA disagrees that it did not follow its own guidance for study quality evaluation and BMD modeling. For additional discussion on the EPA's use of the best available science and

application of EPA guidance, see sections 4.1.1 and 4.1.2 of the EPA response in this *Response to Comments* document.

Second, the commenter points to a common and best-practice statistical approach of evaluating the impact of outliers on model performance and performing regressions excluding outliers from the analysis, if warranted by the data (Rosner, 2015). As illustrated in figure 1 in Dong et al. (2019) and as is typical in NHANES datasets, excluding outliers would not exclude a large proportion of the NHANES dataset as the commenter implied.

Third, the EPA disagrees with the statement that Dong et al. (2019) excluded data based on age. Rather, Dong et al. (2019) quantified correlations between PFAS and serum lipids separately in those age 12-19 and those age 20-80, then further explored associations among adults ages 20 and older in regression models based on the results of the correlation analysis. Conducting analyses for different subgroups of a study population (e.g., children versus adults) is a common best practice when associations are hypothesized to vary in magnitude and direction between groups, as is the case for serum lipid effects in children and adults. Furthermore, the age group included in the regression modeling in Dong et al. (2019) is aligned with the evidence judgement for PFOA/PFOS and serum lipids described in Section 3.4.3.4 of the toxicity assessments, which is primarily based upon significant findings in adults in the general population (USEPA, 2024d; USEPA, 2024c).

Fourth, the EPA disagrees that the final regression models in Dong et al. (2019) were not adjusted for age and gender. In describing the statistical analysis, Dong et al. (2019) state that "…age (12–80 yrs), gender (male or female), race (Mexican-American, other Hispanic, non-Hispanic white, non-Hispanic black or others), family income index (ratio of family income to poverty), body mass index (BMI), waist circumference (WC), physical activities (vigorous, moderate or low physical activity in the preceding 30 days) were included as confounding variables."

Finally, the hybrid modeling approach, described in the *Benchmark Dose Technical Guidance* (USEPA, 2012), cannot be conducted in the EPA's BMDS. Therefore, the EPA must use alternative statistical software to conduct these analyses. The commenter incorrectly implied that there is only one "EPA approved" statistical software. For additional detail on how the EPA conducted BMD modeling, including the use of software and the hybrid approach, see Appendix A, Section A.1.11.2 and Appendix E of the toxicity assessments (USEPA, 2024a; USEPA, 2024b).

Given the commenter's many erroneous claims regarding the quality of the Dong et al. (2019) study, the EPA maintains its position that this is a *medium* confidence study that is suitable for quantitative and qualitative consideration in the PFOA and PFOS toxicity assessments.

3M Company (Doc. #1774, SBC-053451)

EPA states that the sensitive BMR of 5% extra risk was selected for TC models instead of 10% extra risk because use of a 10% BMR would result in a "highly improbable doubling of risk" (see EPA 2023a,b; Table 4-2) because "the percentage of U.S. adults aged 20 and older with total cholesterol ≥240 mg/dL is 11.5%" (EPA 2023b, p. 4-15). In this calculation, EPA erroneously fails to consider the impact of a lack of true control, or "zero exposure" group, on the extra risk calculation since the general population is exposed to at least some measurement of PFAS (see Section 3.9). Before reducing the BMR for models measuring changes in serum TC, EPA did not consider the clinical impact, the confidence in the underlying findings, the biological significance, or the impact of the lack of a true control or "zero exposure" reference on the BMR calculation through extra risk methods. The estimate of 11.5% of US adults with TC ≥ 240 mg/dL may be an underestimate of background high cholesterol in the US; the CDC indicates that, between 2015-2018, 25% of US adults aged 20 or older have hypercholesterolemia or take cholesterol-lowering medications (CDC, 2023). Although EPA does provide the BMD(L)s based on a BMR of 1SD and 0.5SD for Lin et al. (2019; e.g., EPA 2023a, Table E-26) and Steenland et al. (2009; e.g., EPA 2023a, Table E-22), comparisons to a BMR based on a SD change are not provided for Dong et al. (2019, e.g., EPA 2023a, Table E-18), the key study used for POD derivation for TC. It is estimated that, should the EPA use a BMR of 0.5 or 1 SD for deriving a BMDL from Dong et al. (2019), the derived BMDL for PFOA may increase from the selected value of 5% extra risk BMDL of 2.29 ng/mL to 8.12 or 15.5 ng/mL, respectively. Notably, the provided comparisons of BMD(L)s from Lin et al. (2019) and Steenland et al. (2009) based on changes in BMRs do not include the selected BMR of 5% extra risk. It is not clear that EPA consistently used a BMR of 5% extra risk for evaluating all TC studies. Additionally, EPA did not provide justification for use of a 5% extra risk for changes in TC, not hypercholesterolemia incidence, instead of a BMR of 0.5 or 1SD.

EPA Response: The commenter appears misunderstand the modelling approaches for POD derivation used by the EPA. For a detailed response on selection of BMR of 5 percent and on consideration of background exposures, see previous responses to this commenter (e.g., Doc. #1774, SBC-053453) and the rationale the agency provided in the toxicity assessments for PFOA and PFOS (e.g., Section 4.2 of USEPA, 2024d; USEPA, 2024c).

The commenter claims that the EPA failed to provide a comparison of the BMDLs derived for total cholesterol for the critical study (Dong et al., 2019) using a BMR of 0.5 or 1 SD. This is based on an incomplete understanding from the commenter of when such an approach is needed. The modelling approach for Dong et al. (2019) was a hybrid approach using a BMR of 5 percent and the regression slopes from the study. The BMDS approach reported a sensitivity analysis for Lin et al. (2019) or Steenland et al. (2009) is based on mean serum TC or elevated serum TC measures reported by quintile or quartiles of exposures. Such data were not available for Dong et al. (2019) and therefore, this analysis was not conducted (see also the EPA response to comment Doc. #1774, SBC-053444 in section 4.2.2.3 in this *Response to Comments* document).

Raptor Pharm & Tox, Ltd (Doc. #1644, SBC-052846)

Steenland et al 2009

Steenland et al 2009 models predicted total cholesterol, HDL cholesterol, and LDL cholesterol as a function of median PFOA and PFOS levels. As summarized by PennMedicine, dangerous levels of cholesterol levels are: Total > 240mg/dL; LDL > 160mg/dL; HDL < 40mg/dL.

Steenland et al's models demonstrate levels of total cholesterol, LDL, and HDL that are all below the well-accepted dangerous levels. In fact, the levels tend to plateau suggesting that PFOA and PFOS will not drive the levels into dangerous levels at human-relevant concentrations.

This demonstrates that Steenland et al. 2009 has not identified any adverse health outcomes due to PFOA or PFOS exposure. This demonstrates that EPA is using a POD based on this study that is not biologically meaningful, and that PFOA and PFOS are not associated with any adverse health outcomes.

EPA Response: The commenter stated that Steenland et al. (2009) did not identify adverse alterations in serum lipid responses. The EPA disagrees with this comment. As detailed in section 4.2.2 of this *Response to Comments* document, while increases in serum lipid measures such as total cholesterol may not result in changes that would be considered clinically elevated in particular individuals, small changes in the average response of such endpoints can result in substantial health impacts at the population level given the distribution of individual concentrations within the population. The absence of clinically elevated cholesterol levels in Figures 2 and 3 of Steenland et al. (2009) does not imply that such levels would not be observed in the general population, as the model-predicted results in these figures are specific to a subset of relatively healthy individuals (e.g., never smokers, no alcohol use).

4.2.2.3.3 Comments Specific to Alanine Aminotransferase (ALT) Modeling

Raptor Pharm & Tox, Ltd (Doc. #1644, SBC-052847)

Gallo et al. 2012

Gallo et al. also failed to demonstrate an adverse health outcome. A quick review of Table 1 demonstrates that the ALT levels measured in the study are not beyond what is considered a normal ALT level for 87.5% of the population they measured. About 12.5% had an elevated ALT – this is in keeping with the average for the US population with an elevated ALT at any given time. However, it is important to note that an ALT higher than 45 IU/L is not necessarily an indication of any adverse health effect.

ALT by itself is not diagnostic of liver injury. Exercise is well-known to increase ALT levels. Hospital admission itself has been known to increase ALT levels (https://www.ncbi.nlm.nih.gov/pmc/articles/PMC545762/). To be clear, we do not become truly concerned about ALT levels until the levels are very highly elevated (https://www.ncbi.nlm.nih.gov/pmc/articles/PMC545762/).

In this study, the only other biomarkers that may inform on potential liver injury are bilirubin and GGT.

Bilirubin is generally considered a longer-term marker of liver injury, and it is a functional marker as well. In this case, 10x more people have ALT increases compared to the number with bilirubin increases. What we don't know is how many of the people with bilirubin increases also have ALT increases. If we assume they're the same, then this is a very tiny fraction of the overall subjects that have an adverse liver health outcome.

But even still, the models never approach the level of bilirubin, GGT, or ALT, that would be indicative of liver toxicity as a function of PFOA or PFOS. This demonstrates that Gallo et al. 2012 has not identified any adverse health outcomes due to PFOA or PFOS exposure.

This demonstrates that EPA is using a POD based on this study that is not biologically meaningful, and that PFOA and PFOS are not associated with any adverse health outcomes.

EPA Response: The commenter stated that Gallo et al. (2012) did not demonstrate an adverse health outcome associated with PFOS or PFOA and further states that this implies that the EPA is using a POD that is not biologically meaningful. To support this point, the commenter noted that the proportions of study participants with elevated levels of ALT and other liver enzymes were relatively small, and that factors such as hospitalization and exercise could contribute to increased ALT. The EPA disagrees that these points imply the absence of an adverse health outcome. First, as described in Section 4.1.1.1 of the PFOA and PFOS draft and final toxicity assessments, evidence from both epidemiologic and toxicologic studies indicates that elevated serum ALT is associated with clinical liver disease (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c). Second, as detailed in section 4.2.2 of this *Response to Comments* document, small changes in the average response of endpoints such as ALT can result in substantial impacts at the population level given the distribution of individual concentrations within the population (Gilbert and Weiss, 2006). Finally, the presence of a relationship between non-chemical factors (e.g., hospitalization, exercise) and ALT does not imply that elevated ALT is not clinically significant. Additionally, the SAB was supportive of the EPA's consideration of this endpoint and stated, "EPA should use Alanine Aminotransferase (ALT) as an endpoint in light of the numerous studies in the literature that support an association between slight elevations in ALT and increased risk of morbidity and/or mortality" (USEPA, 2022b).

4.2.2.3.4 Comments Specific to Birth Weight Modeling

3M Company (Doc. #1774, SBC-053212)

3. Candidate study selection for developmental effects was not transparent

In reviewing EPA's draft documents, the SAB recommended "that additional clarification and detail be included to support the selection of the critical effect and why this effect, beyond having the lowest PODHED, is the most scientifically appropriate choice as well as being the most protective of public health." (USEPA 2023j, p. 38). In other words, SAB told EPA that it needed to show why critical studies were selected beyond simply having the lowest POD. EPA failed to do so with respect to its analysis of developmental effects.

The IRIS Handbook recommends that only well conducted high or medium confidence human and animal toxicological studies be considered for POD derivation (USEPA ORD 2022). EPA chose 6 studies for POD development for PFOA (Chu et al. 2020; Govarts et al. 2016; Sagiv et al. 2018; Starling et al. 2017; Wikstrom et al. 2020; Yao et al. 2021), and six for PFOS (Chu et al. 2020; Sagiv et al. 2018; Starling et al. 2017; Wikstrom et al. 2020; Darrow et al. 2013; Yao et al. 2021). EPA ultimately chose Wikstrom et al. (2020) for RfD derivation for both compounds. EPA did not describe why these studies were chosen among the multiple medium and high-quality studies for POD derivation, as the SAB requested. Over 30 medium or high confidence studies of birth weight and PFOA were available, and nearly 40 medium or high confidence studies of PFOS and birth weight. All of the studies selected as candidates were rated high confidence, though 4 of the studies measured PFAS later in pregnancy or after delivery, making them subject to biases from pregnancy hemodynamics (Chu et al. 2020; Darrow et al. 2013; Govarts et al. 2016; Starling et al. 2017; Yao et al. 2021). Had EPA's critical appraisal been conducted consistent with recommendations of the SAB and the IRIS Handbook and taken factors specific to PFAS measurement (like timing) into consideration, these studies likely would not have been considered high confidence due to this bias alone.

Both candidate studies selected for the derivation of the RfD for developmental effects measured PFAS in maternal serum taken in early pregnancy – Wikstrom et al. (2020) measured serum PFAS at a median of 10 weeks (range 3-27 weeks), and Sagiv et al. (2018) measured PFAS in a comparable time frame (median 9 weeks; range 5-19 weeks). The Sagiv study also adjusted for estimated glomerular filtration rate (eGFR) to account for blood volume increase and higher flow rate in pregnancy. Despite the additional adjustments for eGFR by Sagiv et al. (2018), Wikstrom et al. (2020) was ultimately used for RfD derivation instead. EPA's rationale for choosing the Wikstrom study over Sagiv is not clear. EPA stated: "The RfD for low birth weight from Wikström et al. (2020) was selected as the basis for the health outcome-specific RfD for developmental effects as it was the lowest and therefore most health protective candidate RfD from these two studies" (USEPA 2023a, p. 4-52, USEPA 2023b, p. 4-48). EPA offered this rationale despite the SAB's recommendation, "that additional clarification and detail be included to support the selection of the critical effect and why this effect, beyond having the lowest

PODHED, is the most scientifically appropriate choice as well as being the most protective of public health" (USEPA 2023j, p. 38).

EPA selected Wikstrom et al. (2020) as "the most scientifically appropriate choice," yet it is unclear whether there were clinically significant birth weight changes, and neither coexposures to other PFAS nor eGFR levels were accounted for in the study's analyses. Thus, EPA failed to follow the SAB's recommendation to provide additional clarification and detail in its justification for outcome-specific study selection other than having the lowest candidate RfD.

EPA Response: This comment is repetitive of others presented by the same commenter. Please refer to the EPA response to comment Doc. #1774, SBC-053452 in section 4.2.2.3.4 in this *Response to Comments* document and Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053452)

Candidate study selection was not transparent.

EPA chose six studies for POD development for PFOA (Chu et al. 2020; Govarts et al. 2016; Sagiv et al. 2018; Starling et al. 2017; Wikstrom et al. 2020; Yao et al. 2021), and six for PFOS (Chu et al. 2020; Sagiv et al. 2018; Starling et al. 2017; Wikstrom et al. 2020; Darrow et al. 2013; Yao et al. 2021). EPA ultimately chose Wikstrom et al. (2020) for RfD derivation for both compounds. EPA did not describe why these studies were chosen among the multiple medium and high-quality studies for POD derivation, as the SAB requested.

Over 30 medium or high confidence studies of birth weight and PFOA were available, and nearly 40 medium or high confidence studies of PFOS and birth weight. All of the studies selected as candidates were rated high confidence, though four of the studies measured PFAS later in pregnancy or after delivery, making them subject to biases from pregnancy hemodynamics (Chu et al. 2020; Darrow et al. 2013; Govarts et al. 2016; Starling et al. 2017; Yao et al. 2021). Had EPA's critical appraisal been conducted appropriately and taken factors specific to PFAS measurement (like timing) into consideration, these studies would not have been considered high confidence due to this bias alone. EPA does not adequately explain its selection of Wikstrom et al. (2020) over Sagiv et al. (2018) or exclusion of the remaining studies.

There were additional critical deficiencies in the studies that EPA used for RfD derivation. EPA stated that although there is no consensus on how best to address PFAS co-exposures, that uncertainty was accounted for in the study quality evaluations and weight of evidence determination for birth weight. However, it was not included in the modifications to the IRIS study evaluation protocol presented in the draft toxicity assessment's Appendix documents and used for critical appraisal. Neither of the candidate studies chosen for RfD determination accounted for PFAS co-exposures in their analyses (Sagiv et al. 2018; Wikstrom et al. 2020), and EPA reviewers noted this limitation for both studies in the HAWC details of the study evaluations.

Despite this critical bias, each study was given an "adequate" rating for the confounding criteria. The authors of Wikstrom et al. 2020 found their single compound analyses to be a limitation, because of simultaneous influences by multiple environmental exposures on health outcomes. Corrections for multiple comparisons were felt to be overly conservative to be suitable for investigations of interrelated PFAS compounds, but the authors called for more carefully designed statistical models, such as mixture-based approaches, to be explored in further studies. EPA was not transparent whether it considered co-exposures to other PFAS as a serious potential bias in the study evaluations. Clear study evaluation criteria are necessary for a thorough appraisal of studies to ensure consistent application and consideration of important factors that may affect the certainty of the findings.

As discussed above, both candidate studies selected for RfD derivation measured PFAS in maternal serum taken in early pregnancy – Wikstrom et al. (2020) measured serum PFAS at a median of 10 weeks (range 3-27 weeks), and Sagiv et al. (2018) measured PFAS in a comparable time frame (median 9 weeks; range 5-19 weeks). The Sagiv study also adjusted for estimated glomerular filtration rate (eGFR) to account for blood volume increase and higher flow rate in pregnancy. Despite the additional adjustments for eGFR by Sagiv et al. (2018), Wikstrom et al. (2020) was ultimately used for RfD derivation instead. The rationale for choosing the Wikstrom study over Sagiv is not clear. EPA stated: "The RfD for low birth weight from Wikström et al. (2020, 6311677) was selected as the basis for the health outcome-specific RfD for developmental effects as it was the lowest and therefore most health protective candidate RfD from these two studies." (EPA 2023a, p. 4-52, EPA 2023b, p. 4-48). This rationale was given despite the SAB recommendation, "that additional clarification and detail be included to support the selection of the critical effect and why this effect, beyond having the lowest PODHED, is the most scientifically appropriate choice as well as being the most protective of public health." (EPA Response to Final SAB Recommendations 2023, p. 38).

EPA selected Wikstrom et al. (2020) as "the most scientifically appropriate choice", yet it is unclear whether there were clinically significant birth weight changes, and neither coexposures to other PFAS nor eGFR levels were accounted for in the study's analyses. Thus, EPA failed to follow the SAB's recommendation to provide additional clarification and detail in its justification for outcome-specific study selection other than having the lowest candidate RfD.

EPA Response: The commenter stated the EPA did not fully describe why the studies selected to derive PODs for PFOA and PFOS were chosen among other *medium* and *high* confidence studies. The commenter stated there were additional deficiencies of the critical studies, namely addressing hemodynamics and PFAS co-exposures, that were not appraised appropriately and should have resulted in a lower confidence rating for studies selected for POD derivation. The commenter stated that the EPA did not provide rationale for the selection of Wikstrom et al. (2020) as the critical study supporting the health outcome-specific RfD over Sagiv et al. (2018), citing model adjustment of estimated glomerular filtration rate (eGFR) as rationale for selecting Sagiv et al. (2018) as the basis for the health outcome-specific RfD. The

commenter stated that the EPA did not provide additional clarification for POD study selection, "beyond having the lowest PODHED," as requested by the SAB.

First, the EPA disagrees with the commenter's claim that the EPA did not provide rationale for why certain studies proceeded to POD_{HED} and candidate RfD derivation. The EPA provides reasons for candidate study selection related to study design and analysis approach (USEPA, 2024d and USEPA, 2024c, Sec. 4.1.1.4) and follows the guidelines outlined in the Appendices (USEPA, 2024a and USEPA, 2024b, Sec. A.1.11.1). The selected candidate studies were the best suited for POD derivation based on their consideration of potential confounding factors (e.g., pregnancy hemodynamics), while study designs and analyses from other *medium* and *high* confidence studies were not as well suited for modeling. Some studies did not present the data or analyses required for dose-response modeling. Due to the high number of *medium* and *high* confidence studies, multiple reasons for including the selected candidate studies were provided (USEPA, 2024d and USEPA, 2024c, Sec. 4.1.1.4). *Low* confidence studies were not considered for POD derivation due to reduced confidence in study results as a result of multiple biases and because there were numerous *medium* and *high* confidence studies to consider.

Second, the EPA maintains that there is no consensus on how best to address PFAS co-exposures, but the EPA included study quality considerations in the updated protocol as described in the toxicity assessment appendices (USEPA, 2024a and USEPA, 2024b, Sec. A.1.2). Further information on the EPA's considerations for potential confounding by co-occurring PFAS has been added to the discussion of addressing uncertainties related to modeling epidemiological studies (USEPA, 2024d; USEPA, 2024b, Sec. 5.1.1). The EPA provided rationale for this in the response to comment Doc. #1774, SBC-053428 in section 4.2.1.2 in this *Response to Comments* document. Briefly, PFAS co-exposures were considered in study quality evaluations, namely the *Confounding* domain (USEPA, 2022a). These considerations resulted in only a very small number of studies being rated *Good* for *Confounding*. Most studies examining birthweight that considered PFAS co-exposures had other deficiencies, such as exposure sampling in later pregnancy or post-delivery. The EPA agrees that sample collection later in pregnancy or post-delivery is a deficincy, which is cited as the rationale for why the EPA selected Wikstrom et al. (2020) and Sagiv et al. (2018) as critical studies for candidate RfD derivation over the others for which the EPA derived PODs (see Section 4.1.5, USEPA, 2024d; USEPA, 2024c). However, the EPA disagrees that it is a deficiency of a magnitude that would result in a reduction of the overall confidence judgment for those studies. The EPA maintains that all of the studies identified for POD derivation for the developmental health outcome should be rated as *high* confidence.

Third, the EPA disagrees Wikstrom et al. (2020) was chosen solely due to having the lowest POD_{HED}. The EPA clearly outlines rationale for the six candidate studies for PFOA and PFOS, as mentioned previously. the EPA specifically outlines why PODs derived from Wikstrom et al. (2020) and Sagiv et al. (2018) were chosen over PODs from other candidate studies (USEPA 2024d and USEPA, 2024c, Sec. 4.1). Selection of these two studies for candidate RfD derivation over the other candidate studies was not based solely on which RfD was most protective. Both studies collected maternal serum samples in early pregnancy, mitigating concerns for changes in

hemodynamics in later pregnancy. The distinction between these two *high* confidence studies relates to their comparability of exposure levels to those experienced in individuals in the United States. Sagiv et al. (2018) was conducted between 1999 and 2002, when PFOA and PFOS exposure concentrations in the United States were much greater. Wikstrom et al. (2020) conducted their study between 2007 and 2010, resulting in exposure levels more similar to those observed in the United States today. While the choice of Wikstrom et al. (2020) was the more health protective candidate RfD, it was also consistent with IRIS Handbook to select studies with "exposures near the range of typical environmental human exposures" (USEPA, 2022a). The EPA has added language clarifying this in the final toxicity assessments (USEPA, 2024d; USEPA, 2024c).

Finally, the EPA considered every comment provided by the SAB PFAS Review Panel. Please see section 4.1.3 of the EPA response in this *Response to Comments* document and USEPA (2023d). In response to public comments, the EPA has continued to improve the transparency and discussion related to candidate study selection, modeling, and RfD derivation. Updates related to these comments are available in Section 4 and Appendix E of the final toxicity assessments (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

3M Company (Doc. #1774, SBC-053453)

For the models based on decreased birthweight, "EPA used the exact percentage (8.27%) of live births in the US in 2018 that fell below the cut-off of 2500 g as the tail probability to represent the probability of extreme ("adverse") response at zero dose." (EPA 2023a, p. E-294 to E-295; EPA 2023b, p. E-22). EPA acknowledges the limitations of using this exact background percentage as it "was calculated without accounting for the existence of background PFOS exposure in the U.S. population" and therefore not explicitly the probability at zero dose (EPA 2023a, p.E-295; EPA 2023b, p. E-22). To adjust for this, EPA estimated the study-specific intercepts of the slope based on the study-reported central tendencies of exposure (e.g., mean or median) and slope; these intercepts were then used to estimate the response in an unexposed population. Although this approach takes into consideration the limitations of having no true unexposed comparison group, it is still limited by assumptions that the model accurately identifies and describes the true intercept, or effect at zero dose. "In this alternative approach, P(0) is 9.86% if there is no background exposure" (EPA 2023a, p.E-295). EPA does not explain its scientific justification for rationalizing an estimated background probability at zero dose that is higher than the observed probability in the US population. This approach also does not fully consider or account for variations in exposure or uncertainties in the estimated slope. Notably, EPA uses the background incidence of LBW and PFAS exposures in the US population to make assumptions of background (or "zero exposure") response, however many of the studies, including the selected key study (Wikstrom et al. 2020) were not conducted in a US population and may have different background responses (e.g., the background LBW incidence in China may be as low as approximately 5%) and PFAS exposures. Regardless of these additional sources of uncertainty, EPA presents the BMD(L) results from these two approaches for decreases in birthweight: with and without the adjustment of the exact percentage of US

background response for background PFAS exposures (EPA 2023a, Table E-15; EPA 2023b, Table E-13). For some studies, the BMD(L)s varied widely with and without adjustment for background exposure (e.g., a range of BMDLs from 63.2 to 90.6 ng/mL for Yao et al. 2021 in the PFOA assessment). However, the BMDL selected for POD derivation for PFOA was not sensitive to adjustments in background exposure; the BMDLs calculated from Wikstrom et al. (2020) ranged from 2.2 ng/mL when the exact percentage of background response was used, as compared to 2.3 ng/mL when the adjusted background was used (EPA 2023a, Table E-15). Therefore, EPA did not make determinations regarding which approach was preferred and instead used the exact percentage estimate since it was the most conservative. For PFOS, the BMDLs calculated from Wikstrom et al. (2020) ranged from 7.7 ng/mL using the exact percentage of response to 9.4 ng/mL based on the alternative tail probability. EPA does not clearly describe why the BMDL from the exact percentage of response was selected, and so it is assumed that EPA again selected the most conservative BMDL. Additionally, EPA examined the impact of assumptions of background exposure on intercept and BMD(L)derivation based on Wikstrom et al. (2020) and show that the BMDL for PFOA could vary from 2.3 to 3.1 ng/mL based on changes in intercept (EPA 2023a, Table E-16). However, these results are not presented for the other considered studies, nor does EPA provide transparency in its reasoning for selecting the BMDL associated with the lowest assumptions of background exposure, even though these assumptions do not match the study-reported background of PFAS exposure of 1.6 ng/mL. Overall, changes in the assumptions regarding the US background of LBW incidence compounded with changes in the assumptions regarding background PFAS exposures could result in a 34-43% change in BMDLs. Additional transparency is needed to discern how this adjusted background approach is applied and incorporated into BMDL selection for the low birth weight POD. EPA did not consistently or transparently report sensitivity analyses used to test these assumptions regarding background incidence or exposure.

EPA Response: The commenter raised concerns with the approaches the EPA used to estimate points of departure from epidemiological studies reporting decreased birthweight. First, the commenter criticized the EPA's assumptions and analyses to account for background PFOA or PFOS exposure and questions differences between the actual and estimated background incidence of LBW. As described in Appendix E.1.2.2, the EPA uses a different set of assumptions to perform sensitivity analyses accounting for background incidence of LBW, as well as background PFOA and PFOS exposure (USEPA, 2024a; USEPA, 2024b). For example, the estimate accounting for background LBW incidence assumes a normal distribution of birthweight, though the actual birthweight distribution observed in the U.S. is slightly skewed (see Table 1 below based on results from CDC wonder site https://wonder.cdc.gov/natality.html). As expected, these differing assumptions result in minor differences between the exact incidence (8.27 percent) of live births falling below the public health definition of LBW and the estimate assuming normal distribution of birthweight (9.86 percent) if there is no background exposure.

Table 1. Birthweight summary based on CDC wonder 2018 data (https://wonder.cdc.gov/natality.html)

Birthweight (g)	Total # of births	# births below cutoff	Percentage of births below cutoff	Percentage of births below cutoff assuming normal (3,261.64, 590.66) quantiles
<2500	3,791,712	313,752	8.27%	9.86%
<3000	3,791,712	1,024,196	27.01%	32.89%
<3500	3,791,712	2,492,835	65.74%	65.67%
<4000	3,791,712	3,494,638	92.17%	89.44%
<4500	3,791,712	3,749,342	98.88%	98.20%

The EPA conducted an additional sensitivity analysis specific for the critical study (Wikstrom et al., 2020) that accounts for variation in exposure (see Appendix E of USEPA (2024a) and (2024b)). These analyses incorporated variation in exposure (i.e., 4.6 ng/mL for PFOA and 23.8 ng/mL for PFOS), as well as variation in the incidence of LBW (i.e., as low as ~5 percent). The uncertainty in the estimated slope was accounted for by the CI of the slope. Additionally, comparisons of BMDLs across different studies can provide insight into potential uncertainty in the estimated slope.

Second, the commenter notes that many of the studies modeled by the EPA were not conducted in the U.S. population which increases the uncertainty of conclusions based on these studies. The EPA disagrees with this commenter's conclusion. Please see section 4.2.2 of the EPA response in this *Response to Comments* document. Unless there are data showing otherwise, it is reasonable to assume that populations outside the U.S. would generally show similar responses (i.e., have a similar slope) as the U.S. population. The commenter does not provide a citation supporting their assumption that background LBW incidence in China is significantly different than background incidence in the U.S. However, given these uncertainties, the EPA derived multiple candidate BMDLs representing different study populations in both the draft and final toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c).

Third, the commenter criticizes the EPA's use of the exact LBW incidence in the agency's selected modeling approach. The commenter states the EPA selected BMDLs based on exact percentage because it is more conservative and was not transparent in its decision making. The EPA disagrees with these criticisms but has provided additional discussion in Appendix E to clarify the rationale (USEPA, 2024a; USEPA, 2024b). When the background PFOA or PFOS exposure is relatively high, the BMDL estimated from the alternative probability approach may be preferred as the background exposure should not be neglected in these populations. This is reflected in the differences between BMDLs derived for PFOA (but not PFOS as the exposure concentrations are relatively low) using the two approaches for the Yao et al. (2021) study, as raised by the commenter. As the PFOA exposure reported by Yao et al. (2021) is relatively high (median PFOA exposure of 42.8 ng/mL), the difference in the BMDLs produced by the two approaches is greater than for other studies reporting lower exposure levels. However, *because*

the PFOA exposure reported by Yao et al. (2021) is so high, EPA determined the PFOA levels were not comparable to the U.S. general population and therefore did not use BMDLs from Yao et al. (2021) as the basis of points of departure (PODs) for PFOA (see USEPA, 2024d; USEPA, 2024a). Studies such as Wikstrom et al. (2020) reported lower PFOA and PFOS exposure levels (median PFOA exposure of 1.6 ng/mL), which are comparable to the U.S. general population (i.e., compared to results from the ACE Biomonitoring on Perfluorochemicals program), and produced less variability between BMDLs. In cases where background exposure is unlikely to be driving the response (i.e., when background levels are relatively low), it is reasonable for the EPA to use the exact percentage in the U.S. population to support BMD modeling rather than the alternative model which relies on additional assumptions. Regardless, for studies reporting PFOA and PFOS levels similar to those seen in the U.S., the differences between BMDLs derived from the actual and alternative approaches are minimal (i.e., modeling of 4/6 PFOA studies results in BMDLs differing by ≤ 0.1 mg/L; modeling of 4/6 PFOS studies results in BMDLs differing by ≤ 1.7 mg/L).

Finally, the commenter notes that the EPA only provides additional analyses on the influence of background exposure from Wikstrom et al. (2020). In the draft toxicity assessments supporting the proposed rule, the EPA provided sensitivity analyses (see Table E-16 in PFOA (USEPA, 2023b) and E-14 in PFOS (USEPA, 2023c)) for Wikstrom et al. (2020), as it was ultimately selected as the critical study and served as the basis for the health outcome-specific RfD for developmental effects. After considering the commenter's input, the EPA has added similar analyses for each study considered for POD derivation to the final toxicity assessments. These analyses are now presented along analyses from Wikstrom et al. (2020) in Appendix E (USEPA, 2024a; USEPA, 2024b).

4.2.2.4 Derivation of Cancer Slope Factors (CSFs)

New Hampshire Department of Environmental Services (Doc. #1690, SBC-044339)

For the proposed CSFs for the HHRA (Page 18656, Column 2) as well as the Benefits Analysis (Section XIII-Health Risk Reduction and Cost Analysis – Page 18689, Column 3), EPA should further clarify the uncertainties about exposure levels used to estimate the CFSs for PFOA. EPA does not provide any analysis (e.g., sensitivity analysis) to determine the impact of its assumption that serum PFOA levels are stable over time between the onset of a disease and the time that single exposure measures are collected.

EPA Response: As described in the EPA response to comment Doc. #1774, SBC-053147 in section 4.2.2.4 in this *Response to Comments* document and section 4.2.2 of the EPA response in this *Response to Comments* document, the EPA maintains its conclusions that reliance on a single serum PFOA measurement is adequate to estimate the CSF for PFOA. This is because of the long half-life of this compound, which results in relatively stable serum concentrations over time. Discussion on the half-life and uncertainties in the available literature was presented in Section 3.3.1.4.5 of the PFOA draft toxicity assessment (USEPA, 2023f).

3M Company (Doc. #1774, SBC-053147)

1. Evidence for PFOA Carcinogenicity and Derivation of the Cancer Slope Factor

EPA failed to apply applicable guidance in evaluating the evidence of carcinogenicity and deriving a CSF for PFOA. EPA's IRIS Handbook indicates that "consistency across studies or experiment" should be considered as part of the evidence synthesis step. Additionally, EPA's Cancer Risk Assessment Guidelines (USEPA 2005) recommend that, "[w]hen multiple estimates [of cancer risk] can be developed, all datasets should be considered, and a judgment made about how best to represent the human cancer risk."

Contrary to this guidance, the proposed rule makes clear that EPA failed to consider all datasets relevant to potential cancer risk. As discussed below, in evaluating carcinogenicity, EPA incorrectly excluded several occupational exposure studies (Steenland and Woskie et al. 2012; Raleigh et al. 2014; Barry et al. 2013) which collectively demonstrate limited or no association with kidney cancers among workers with 10- to 100-fold greater exposure to PFOA than seen in the general population. Instead, EPA relies on Shearer et al. (2021), a matched casecontrol study on kidney cancer (324 cases, 324 matched controls) from the Prostate, Lung, Colorectal, and Ovarian Screening Trial (PLCO), which has critical flaws, as detailed below (e.g. a single serum measurement, potential reverse causation), that undermine the integrity of EPA's conclusion.

a. EPA incorrectly excluded occupational studies with greater exposures than Shearer et al. (2021)

Steenland and Woskie (2012) is an occupational cohort mortality study of DuPont workers (n = 5,791) with PFOA exposures, which reported a total of 12 kidney cancer deaths. This study observed significant elevated risk of kidney cancer death only in the highest exposure quartile. EPA identified this as a medium confidence study but stated that it did not consider it further because of the small number of observed cancer cases and because "information on a range of exposures more relevant to the general population were available from Shearer et al. (2021)" (USEPA 2023a). However, the range of exposures in Steenland and Woskie (2012) was actually 10 to 100 times higher than the general population, an indication that kidney cancer is not associated with general population-levels of exposure to PFOA.59

EPA also improperly excluded Barry et al. (2013), which is a community/worker cohort study of 32,254 residents (28,285 community members and 3,713 DuPont workers) with residential exposure to PFOA in their drinking water for which there were a total of 105 kidney cancer cases (87 from the community and 18 from the DuPont workers). This study also did not find a significant association of kidney cancer cases among workers who had serum concentrations that were 10-fold greater than the community population in Shearer et al. (2021). EPA stated Barry et al. (2013) was not suitable for dose-response analysis because it was performed in the same study area as Vieira et al. (2013) and may involve a number of the same participants. In addition, EPA stated that Barry et al. (2013) lacked the necessary exposure measurements for CSF calculation. However, a later study, Bartell and Vieria (2021), reports the necessary exposure data

from Barry et al. (2013), which EPA did not acknowledge or explain why these data did not make this study appropriate for inclusion in its analysis, and thus arbitrarily excluded Barry et al. (2013).

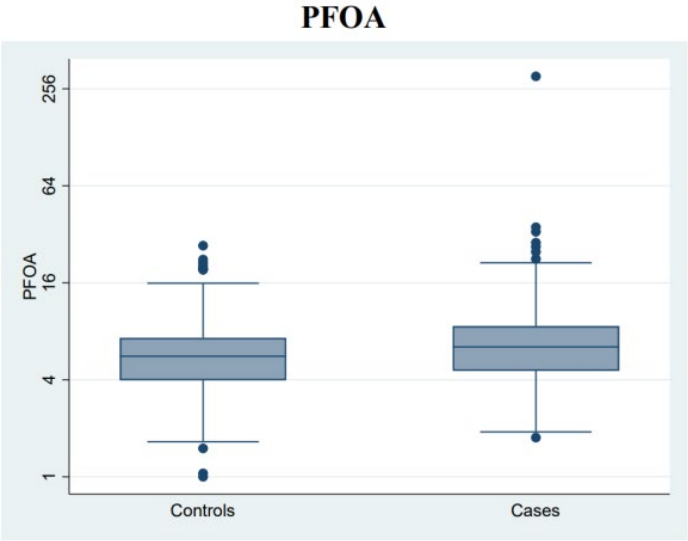
EPA also incorrectly excluded Raleigh et al. (2014), reportedly based on concerns of exposure assessment methods and study quality as well as the small number of cases (USEPA 2023a). Raleigh et al. (2014) is an occupational cohort mortality and cancer incidence study of 3M workers (n= 4,668) with exposure to the manufacture of the ammonium salt of PFOA (i.e., APFO) that reported 16 kidney cancer cases and was not confounded by TFE exposure. The authors did not find an excess of kidney cancer cases beyond what would be expected in the general population. EPA stated that it excluded this study because it used modeled estimates of PFOA air concentrations in the workplace rather than biomonitoring measurements and because of concerns about absorption of inhaled PFOA. However, EPA did not appropriately consider the totality of other studies that found that these workers did likely have high PFOA exposures consistent with the higher PFOA serum concentrations (Olsen et al. 2000, 2003; Raleigh et al. 2013, 2014). Other studies have also concluded that PFOA is efficiently absorbed in rodents following inhalation of PFOA (Griffith and Long 1980; Kennedy et al. 2004). Therefore, EPA mischaracterized the quality of the data from Raleigh et al. (2014), resulting in the arbitrary exclusion of this study.

EPA's failure to collectively synthesize evidence from the occupational exposure studies resulted in a misinterpretation of the weight of evidence. Though individually the three occupational studies may not have been suitable to calculate a CSF, EPA failed to consider that, collectively the PFOA exposures in these three worker studies were one to two orders of magnitude greater than the general population serum PFOA concentrations reported in Shearer et al. (2021) yet showed little to no association with kidney cancer.60 In Shearer et al. (2021), 324 kidney cancer cases originated from a cohort of 150,000 adults aged 55 – 74 with kidney cancer cases representing 0.22% of the cohort. In the three occupational cohorts by Steenland and Woskie (2012), Raleigh et al. (2014), and Barry et al. (2013) which had cohorts of 5,791, 4,668, and 3,713 (total = 14,172) workers respectively, there were a total of 52 kidney cancer deaths and cases representing 0.37% of the combined three cohorts. Though EPA labels each of these as small studies, they are collectively comparable to Shearer et al. (2021) in the percentage of kidney cancer cases.61

Therefore, among these three occupational analyses, which likely represent the highest exposed individuals based on overall reported biomonitoring data, only one analysis (Steenland and Woskie 2012) showed a statistically signficant associaton with kidney cancer, but this was confounded by the authors' decision to not adjust for TFE exposure. EPA did not synthesize the evidence across these studies, as is recommended by the IRIS Handbook and Cancer Guidelines, to inform its approach to the CSF and as a result did not appropriately assess the overall weight of evidence for carcinogenicity.

b. EPA did not properly assess Shearer et al. (2021) for flaws that undermine its reliability

Because EPA excluded the above occupational studies from consideration for the CSF, it instead inappropriately relied solely on Shearer et al. (2021) where a single measurement of serum PFOA was used to calculate the CSF.



Both EPA and Shearer et al. state the long half-life of elimination of PFOA indicates that a single serum measurement could be sufficient to provide an accurate and precise measurement of a person's long-term PFOA exposure. This assertion ignores the considerable uncertainty regarding the distribution, calculation, and measurement biases associated with the serum elimination half-lives of PFOA in humans as discussed in a series of publications (Dourson and Gadagbui 2021; Campbell et al. 2022a,b; Post et al. 2022). Shearer et al.'s (2021) conclusion that a single PFOA measurement is sufficient based on PFOA's long-half life in humans contradicts fundamental considerations of the connection between toxicodynamics, toxicokinetics, and time (Rozman et al. 1996). This highlights the limitations of using serum concentrations measured 2 to 18 years prior to the diagnosis of the disease. If the serum elimination half-life ranges from 0.5 to less than 3.0 years, then a PFOA measurement taken, on average, 8.8 years prior to the diagnosis of kidney cancer could be anywhere from 3 to greater than 5 half-lives from the diagnosis of kidney cancer. This discrepancy limits the accuracy of the reported serum concentrations in Shearer et al. (2021).

Shearer et al. (2021) also did not appropriately address reverse causation, which is a type of pharmacokinetic bias (Andersen et al. 2021) and occurs when a physiological outcome (e.g., estimated glomerular filtration rate [eGFR]), which affects the exposure assessment, has been moderated by the health outcome itself. The pharmacokinetic bias occurs when there is a sufficient window of time for the disease state to influence physiological factors that can bias the exposure assessment. EPA's IRIS Handbook recommends evaluating epidemiological studies for reverse causality and if reverse causality is a concern in the observed association of the exposure and health outcome, then a study should be labelled as deficient or critically deficient. In Shearer et al. (2021), the lack of an association between eGFR, PFOA, and kidney cancer does not

conclusively demonstrate a lack of reverse causation, but it should have been considered as a factor because the eGFR was measured, on average, 8.8 years prior to the diagnosis of kidney cancer. There is the possibility of pre-diagnostic conditions that result in declining renal function. EPA therefore violated its own guidance in suggesting the lack of an association between a single eGFR measurement, and the diagnosis of kidney cancer eliminates the concern about this type of pharmacokinetic bias in the association between the exposure to PFOA and kidney cancer.

c. EPA uses inconsistent methods to calculate the cancer slope factor resulting in an overly conservative value

The cancer slope factor (CSF) describes the relationship between dose and cancer risk. EPA considers the slope factor as the upper-bound estimate of risk per increment of dose that can be used to estimate risk of cancer for different exposure levels (USEPA 2005). Thus, a steeper slope, or greater CSF, indicates that cancer risks are expected to increase more per each unit increase in dose. EPA's Cancer Guidelines (USEPA 2005) state that CSFs are derived for substances that are assumed to have a linear no-threshold mode of action or as a default if a different mode of action cannot be identified. This means that EPA assumes that even at doses below a carcinogenic point of departure, there is a nonzero risk of cancer. CSFs can be derived from either animal or human studies but should be derived based on the best practices in EPA's Cancer Guidelines.

EPA's derivation of the CSF lacks transparency and EPA inconsistently selects studies and analysis techniques, resulting in a CSF that is not based on the best available data. EPA relied solely on the relative risk of renal cell carcinoma from Shearer et al. (2021) to calculate the CSF, which as described above has critical limitations that make it unreliable. EPA's CSF derivation is based on a simple regression model originally used by the California Office of Environmental Health Hazard Assessment (OEHHA) (CalEPA 2021; OEHHA 2004), which is used to estimate the dose-response between PFOA and renal cell carcinoma risk. The CSF is then calculated as the excess cancer risk associated with each ng/mL increase in serum PFOA (internal CSF).

Results of EPA's analysis of Shearer et al. (2021) are reported in Table E-42 in the PFOA MCLG Appendix excerpted below. PFOA dose levels in each quartile of exposure (represented as xi) were supposedly calculated as the midpoint of the reported PFOA range in ng/mL from Shearer et al. (2021). However, as seen in the second and third rows of excerpted Table E-42 below, the xi values of 2.75 and 4.4 are not within their respective PFOA ranges in the leftmost column. Thus, these values do not actually represent the midpoint of the categories used by Shearer et al. (2021).

Table E-42 from the PFOA MCLG Appendix demonstrating the odds ratios for PFOA serum concentrations and renal cell carcinoma from Shearer et al. (2021).

[Table E-42: see docket ID EPA-HQ-OW-2022-0114-1774]

Based on the analysis outputs in Table E-43 of the PFOA MLCG Appendix, EPA calculates the CSF of 0.00352 (ng/mL)-1 which represents the upper 95th percentile of the slope.

EPA also calculated CSFs based on Vieira et al. (2013) which is a study based on 58 kidney cancer cases exposed via drinking water and compared to greater than 7,000 controls. EPA calculates CSFs by either including or excluding the highest exposure level from that study (Table E-43 PFOA MCLG Appendix). EPA failed to explain why it chose not to use the regression model provided by California's Office of Environmental Health Hazard Assessment (OEHHA) and instead used the midpoint ranges of the Vieira et al. (2013) categorical data. This practice is inconsistent with the approach EPA applied to Shearer et al. (2021) to derive the CSF. This inconsistency of methods to derive a CSF from these two studies is arbitrary, lacks sufficient justification, and in the absence of a sensitivity analysis, prevents understanding of the ramifications of this arbitrary choice.

It is important to note that EPA's and OEHHA's approach to the derivation of the CSF are distinctly different and when followed with the same datasets, will result in different CSFs. OEHHA chose to use the central estimate of the slopes (i.e., the slopes themselves). This is because OEHHA combined the results of two separate studies (i.e., Shearer et al. 2021 and Vieira et al. 2013) to develop its final overall CSF. OEHHA determined this combination of different studies and different study sites would account for much of the variance likely to occur across different PFOA-kidney cancer sites and therefore using the geometric mean of the two slopes was a better representation of potential cancer risks across the general population. In contrast, because EPA did not appropriately synthesize the evidence, it only relied on Shearer et al. (2021) and instead based its estimate of the slope on the upper 95th percent confidence interval. Thus, California's CSF of 0.00178 (ng/mL)-1 is approximately half that of EPA's CSF of 0.00352 (ng/mL)-1 . Notably, the California CSF is nearly identical to the CSF derived from the pooled data analysis of the Shearer et al. (2021) and Barry et al. (2013) as published in Steenland et al. (2022). [FN62: Steenland et al. (2022), which calculated a CSF from pooled data from Shearer et al. (2021) and Barry et al. (2013), recognized that the CSF derivations from Shearer et al. and Barry et al. were statistically different due to differences in the dose-response relationship at different exposure levels.] Additionally, EPA's Cancer Guidelines allow for "combining data from different datasets in a joint analysis" (USEPA 2005, p. 3-25). Therefore, EPA should have considered this approach, which may better reflect the overall evidence base.

EPA Response: The commenter stated that the EPA did not follow its own guidance in evaluating the evidence base or deriving a CSF for PFOA. The commenter stated the EPA did not consider consistency across studies and cited the EPA guidance stating that multiple estimates of cancer risk should be developed when possible. The EPA disagrees with these claims. As described in the draft toxicity assessment (USEPA, 2023f), the EPA followed the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) when conducting the cancer assessment for PFOA and protocols outlined in the *IRIS Handbook* (USEPA, 2022a) when synthesizing and integrating evidence across the epidemiological, animal toxicological, and mechanistic evidence streams. The EPA described and considered every study the commenter recommended and particularly noted consistencies across the evidence base (see Section 3.5, USEPA (2023f)). Additionally, the EPA developed multiple estimates of cancer risk (i.e., CSFs) for both epidemiological and animal toxicological studies. These candidate CSFs for kidney cancer in humans (Shearer et al., 2021;

Vieira et al., 2013) and hepatocellular, pancreatic, and LCTs in rats (NTP, 2020; Butenhoff et al., 2012) were presented in Section 4.2 (USEPA, 2023f). All of this information is similarly presented in the final toxicity assessment for PFOA (USEPA, 2024d; USEPA, 2024a).

The commenter stated that the EPA incorrectly excluded occupational studies providing results for kidney cancer, including Steenland and Woskie (2012), Barry et al. (2013), and Raleigh et al. (2014). The commenter specifically cited higher ranges of exposure reported in these three studies, and particularly by Steenland and Woskie (2012), as evidence that effects do not occur at ranges found in the general population. The commenter stated Barry et al. (2013) was improperly excluded from POD derivation because the study was included in a later meta-analysis (Bartell and Vieira, 2021). The commenter stated Raleigh et al. (2014) was inappropriately excluded, citing animal evidence for inhalation absorption of PFOA. The commenter stated that the EPA did not collectively synthesize evidence from these three occupational studies.

The EPA disagrees with the commenter's interpretation of results from Steenland and Woskie (2012). The commenter correctly points out the significant association between elevated exposure to PFOA and an increased risk of kidney cancer mortality (Steenland and Woskie, 2012). The commenter suggests that the fact the association reported by Steenland and Woskie (2012) is only observed in the highest exposure group reduces the impact of the associations observed at general population exposure levels (i.e., the significant increased risk of kidney cancer observed in Shearer et al. (2021)). However, there is an important difference between these two studies; namely, Steenland and Woskie (2012) reported associations between elevated PFOA exposure and kidney cancer mortality while Shearer et al. (2021) reports the risk for incident kidney cancer. Methods in the IRIS Handbook state that "data on incident cases are generally preferred over mortality data" (USEPA, 2022a) for exposure-response modeling. Further, according the EPA's *Guidelines for Carcinogen Risk Assessment*, analyses of cancer mortality can be improved by adjusting to reflect the incidence-mortality relationship because survival rates vary between cancers (USEPA, 2005), and Steenland and Woskie (2012) did not conduct such an analysis. Additionally, the commenter raised concerns with the study regarding potentially confounding exposures (i.e., TFE [Trifluroethanol]) and an error in the reporting of exposure ranges. The commenter stated the error in reporting of exposure ranges from Steenland and Woskie (2012) would result in exposure levels "more relevant to the general population." However, this directly contradicts the commenter's earlier claim that higher exposure levels would be "an indication that kidney cancer is not associated with general population-levels of exposure to PFOA." Both concerns raised in the footnote (i.e., potential confounding by TFE exposure and the reporting error) further provide support for the EPA's decision to not move the study forward for dose-response modeling (see USEPA, 2024d). Interestingly, the concerns raised by the commenter were drawn from a meta-analysis which concluded that there is a significant increase in risk with increasing exposure to PFOA (Bartell and Vieira, 2021), which is in agreement with the EPA's conclusion that PFOA is *Likely to be Carcinogenic to Humans* (USEPA, 2024d).

The EPA disagrees that Barry et al. (2013) was arbitrarily excluded from POD derivation. Vieira et al. (2013) was selected over Barry et al. (2013) due to the overlapping populations between the two studies; Vieira (2013) included the most complete and up-to-date data from this population. In addition, Barry et al. (2013) was not modeled because the study did not provide exposure levels for the entire population (exposure data were reported separately for the community participants and workers), which was necessary information to include in the CSF calculation (USEPA, 2023a, Sec. E.1.5). The EPA has provided additional discussion on candidate study selection to Section 4.1 of the final toxicity assessments for PFOA and PFOS which includes a discussion of studies with overlapping populations (USEPA, 2024d; USEPA, 2024b, Sec. 4.1). Because Vieira et al. (2013) provided updated data on the same population, the EPA did not also reach out to Barry et al. (2013) for combined exposure concentrations.

Regarding Raleigh et al. (2014), lack of biomonitoring data remains a concern and is justification for the EPA's determination that this is a *low* confidence study and therefore, should not be prioritized for POD derivation (USEPA, 2024d; USEPA, 2022a). As noted in the appendix (USEPA, 2024a) and Bartell and Vieira (2021), there is still a lack of information on determining human absorption of PFOA through inhalation. Additional information from Raleigh et al. (2014) would be required to estimate the absorbed dose in humans, thus resulting in the study being excluded from POD derivation.

The EPA disagrees that the agency did not collectively synthesize all three studies in the cancer assessment for PFOA. The EPA examined the weight of evidence across all studies reporting on cancer outcomes, and kidney cancer was selected for CSF derivation based on all the studies reviewed (USEPA, 2024d, Sec. 3.5.4). In contrast to the commenter's assertion that these studies did not provide consistent support for kidney cancer, all three studies observed either significant (Steenland and Woskie, 2012) or non-significant (Barry et al., 2013; Raleigh et al., 2014) increases in the risk of kidney cancer associated with PFOA exposure. A change or result that lacks statistical significance can be used to support a conclusion of an effect (Wasserstein and Lazar 2016; USEPA, 2022a). Additional evidence from a recent meta-analysis and a pooled analysis (Bartell & Vieira, 2021; Steenland et al., 2022) support the EPA's conclusion that PFOA exposure is associated with increased risk of kidney cancer.

The commenter stated numerous concerns regarding the EPA's decision to rely on Shearer et al. (2021) as the basis of the CSF for PFOA. However, the commenter criticized Shearer et al. (2021) but cites other peer-reviewed publications that quantitatively rely on this study as the basis of CSFs for PFOA in their rationale (CalEPA, 2021; Steenland et al., 2022). The commenter stated the CSF derived from the estimate reported in Shearer et al. (2021) was inappropriate because it was based on a single estimate of exposure. The commenter suggested this is inappropriate as the time between exposure measurement and average diagnosis was greater than the elimination half-life for PFOA. As stated in section 4.2.2 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045682 and Doc. #1774, SBC-045683 in section 4.1.4.3 in this *Response to Comments* document, the EPA disagrees with the commenter's characterization of the representativeness of

single measurements for PFOA and PFOS. In addition, adequate study of cancer outcomes requires consideration of the latency period of the disease. Cancer is not an acute outcome that develops immediately following chemical exposures. The study's measurement of PFOA 2-18 years prior to diagnosis in adults aged 55 years and older was appropriate considering the nature of the outcome of interest.

The exposure levels reported in Shearer et al. (2021) were also analyzed in the California EPA's assessment to assess applicability to general population exposures (CalEPA, 2021). Based on historic PFOA production levels, data from smaller studies, and NHANES exposure concentrations, CalEPA concluded that serum PFOA concentrations collected in Shearer et al. (2021) were similar to those in the general U.S. population and representative of participants' peak exposure levels. Considering the latency period for most cancer diagnoses, the exposure levels reported in Shearer et al. (2021) would be representative of relevant exposure windows for the development of cancer.

The commenter stated that the lack of association between eGFR, PFOA, and kidney cancer prior to diagnosis does not preclude the presence of reverse causality in Shearer et al. (2021) and that the EPA did not accurately evaluate the study as a result. The EPA disagrees that reverse causality was not considered and addressed in the evaluation of Shearer et al., (2021). The EPA evaluated the study according to its own PFAS-specific exposure assessment criteria (USEPA, 2024a and USEPA, 2024b, Sec. A.1.7.1.3; USEPA, 2021a), which is reflected in the study quality evaluation for Shearer et al., (2021) (see Section 3.5 of USEPA, 2024d; USEPA, 2024c). Based on the analysis provided by the authors, there was no direct evidence that reverse causality was present or had not been mitigated by the study's design. Decisions to downgrade domains to *Critically Deficient* or studies to *Uninformative* are not based on indirect evidence or assumptions. Additionally, other studies reporting on kidney cancer did not consider eGFR as a potential confounder. As a result, Shearer et al., (2021) was the only study to demonstrate a lack of association between eGFR and incidence of kidney cancer at any point throughout the study. The commenter did not provide evidence supporting their assertion that reverse causality was a significant factor that impacted the findings of Shearer et al. (2021) or any other study of kidney cancer considered in this assessment.

The commenter stated the EPA's CSF was derived from a study, Shearer et al. (2021), with critical limitations and suggested that this makes the CSF unreliable. The EPA responded to the commenters concerns regarding Shearer et al. (2021) above and disagrees that these concerns result in an unreliable CSF.

The commenter additionally cited data from the EPA's analysis of Shearer et al. (2021) from the Appendix and suggested that a mistake had been made but in actuality mischaracterized the EPA's approach (USEPA, 2023b). Regarding the quartile midpoints, the EPA documented its approach in the Appendix (USEPA, 2023b, Sec. E.1.5.1.2). Specifically, "[s]ince the intercept of the regression is set at 1 for a dose of 0, the midpoint of the lowest quartile was subtracted from each of the midpoint of the upper quartiles." For example, the Quartile 1 xi value (2.0) was subtracted from the midpoint for Quartile 2 (4.75), yielding an adjusted midpoint value (2.75).

The commenter raised concerns with the EPA's derivation of a CSF based on data from Vieira et al. (2013), suggesting the EPA did not justify the decision to not use the same regression model as CalEPA's assessment (CalEPA, 2021) or the same approach as done with Shearer et al. (2021). The commenter appears to misunderstand how the EPA derived CSFs. First, the EPA did not rely on the regression model from CalEPA; the agency conducted its own modeling, as presented in Appendix E (USEPA, 2023b). The EPA disagrees that sufficient justification for modeling decisions related to deriving a CSF from Vieira et al. (2013) was not provided. The EPA used the same approach in modeling the data from Vieira et al. (2013) as the method used for modeling the data from Shearer et al (2021). The approach and results are presented in detail in Section E.1.5 of the PFOA Appendix (USEPA, 2024a).

The commenter incorrectly stated that the EPA did not consider a pooled analysis approach using data from Vieira et al. (2013) and Shearer et al. (2021) as was completed by CalEPA (2021). A sensitivity analysis combining the data was described in the Appendix (USEPA, 2023b, Sec. E.1.5.1.3). One approach included pooling the study-specific slopes using a random effects REML approach, and another approach was to take the geometric mean of the study-specific CSF_{serum}. However, as previously noted, there were considerable differences between Shearer et al. (2021) and Vieira et al. (2013), "including outcomes considered (RCC *vs*. any kidney cancer), exposure assessment (serum biomarker *vs.* modeled exposure), source population (multi-center nationally *vs.* Ohio and WV), study size (324 cases and 324 matched controls *vs.* 59 cases and 7585 registry-based controls)" (USEPA, 2023b, E.1.5.1.3). The EPA concluded that these differences limit the viability of deriving a CSF based on the pooled data (USEPA, 2024d). The commenter noted a similar approach taken by Steenland et al. (2022) to derive a pooled RfD between Shearer et al. (2021) and Barry et al. (2013). Considering Barry et al. (2013) was performed in the same study area as Vieira et al. (2013), likely involving many the same participants, the study was also considerably different from Shearer et al. (2021) and would similarly limit the viability of this approach.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053423)

EPA also inappropriately developed slope factors for PFOA and PFOS. While the SAB agreed that robust human epidemiological data is preferable when available, it stated in its report to EPA that "for PFOA, there is an absence of 'high confidence' epidemiologic data as summarized by EpA." [FN136: Id. at 39.] One of the reasons for this lower confidence is that epidemiological data available (presented in a Shearer et al. 2021 study assessing kidney cancer risk) was not fully evaluated for the impacts of one individual in the study who had elevated serum PFOA levels. [FN137: Id.] For these reasons, and others described in the SAB report, the SAB recommended that EPA develop multiple candidate cancer slope factors (CSFs) including values based on animal cancer bioassays, and SAB did not endorse using the Shearer et al. study that EPA relied upon in the 2021 Draft Assessment. Despite the lack of endorsement from the SAB, and the concerns expressed by the SAB regarding how the slope factor from the human studies did not align with the animal evidence, EPA continues to rely on the Shearer et al. 2021 study. In this proposal, EPA does not provide a scientific explanation to address the SAB concerns

regarding the Shearer et al. study. Rather, EPA attempts to justify its choice by pointing to an EPA Office of Research and Development (ORD) Staff Handbook which states "when both laboratory animal data and human data with sufficient information to perform exposure-response modeling are available, human data are generally preferred for the derivation of toxicity values." [FN138: See Public Comment Draft Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) in Drinking Water, Mar. 2023, at page 4-49.] EPA's rationale is misleading. This ORD guidance is merely repeating the same general admonition acknowledged by the SAB that using human data is preferrable if it is available and robust. It by no means is forcing EPA to rely on the lower confidence Shearer et al. study. EPA should not finalize this proposal without squarely addressing the SAB recommendations to discuss the strengths and limitations of different CSFs [FN139: See SAB report to the EPA Administrator Aug. 22, 2022, at pages 42, available at: https://sab.epa.gov/ords/sab/f?p=100:18:16490947993:::RP,18:P18_ID:2601#report.].

EPA Response: The commenter stated that the SAB did not endorse the PFOA CSF based on the Shearer et al. (2021) epidemiological study and the EPA did not address the concerns raised by SAB regarding this study or the strengths and limitations of different CSFs. The EPA disagrees with these statements and the commenter's characterization of the SAB's feedback. In its final report (USEPA, 2022b), the SAB stated: "At least one new study, the general population nested case-control study conducted in the PLCO cohort (Shearer et al., 2021), supports previous positive associations with kidney cancer observed in individuals highly exposed to PFOA," and the SAB requested "a clear rationale for its selection as the sole basis for the CSF should be provided," as well as additional details regarding the modeling of this study. The SAB did not explicitly state that the EPA should not rely on the Shearer et al. (2021) but requested more rationale for the EPA's selection and modeling approach, which was provided in the draft toxicity assessment (Section 4.2; USEPA, 2023f), appendix (Appendix E; USEPA, 2023b), and the response to SAB comments document (USEPA, 2023d). The SAB panel also agreed that "toxicity values should only be derived from studies with at least 'medium' confidence," (USEPA, 2022b) which conflicts with the commenter's implication that because the EPA determined Shearer et al. (2021) to have a rating of *medium* confidence, it is not adequate for toxicity value derivation. The commenter implies that Shearer et al. (2021) was "lower confidence" because it did not account for an individual with an outlier PFOA concentration. The EPA disagrees that Shearer et al. (2021) was rated "lower confidence" due to this outlier. The study was considered *medium* confidence, consistent with agency systematic review methods (USEPA, 2022a; USEPA, 2021a; USEPA, 2024a; USEPA, 2024b) and the study authors provided multiple analyses, including continuous models of exposure as well as an analysis by quartile of exposure. Elevated ORs for the risk of RCC were observed for participants in the second and third quartiles of PFOA exposure compared to the first quartile of PFOA exposure, which would not include the outlier PFOA exposure concentration. The EPA also notes that the SAB recommended the EPA consider modeling other epidemiological studies reporting associations between PFOA and kidney cancer, indicating that they support the use of epidemiological data for toxicity value derivation (USEPA, 2022b).

The commenter stated the slope factor from the human studies did not align with the animal evidence. Discussion on comparisons between toxicity values derived from animal toxicological studies and epidemiological studies was presented in Sections 4.1.6 and 6.2 of the PFOA draft toxicity assessment (USEPA, 2023b; now Sections 4.1.6 and 5.2 of the final toxicity assessment, USEPA (2024a)). Though the former was in context of the candidate RfDs, the rationale is similarly applicable to derivation of candidate CSFs.

The EPA disagrees that the agency's rationale for the selection of a CSF based on an epidemiological study over the CSFs derived for animal studies was misleading and refers the commenter to section 4.2.2 of this *Response to Comments* document. The EPA concluded that the available data reported consistent positive associations between PFOA and kidney cancer in various study populations and therefore, the derivation of a CSF based on epidemiological evidence was warranted (USEPA, 2024a).

American Chemistry Council (ACC) (Doc. #1841, SBC-044828 & SBC-044829)

Shearer et al. Should Not be Used to Derive a Cancer Slope Factor for PFOA

Shearer et al. identified 324 cases of RCC among 75,000 participants of a multi-site study from medical centers in ten US cities. [FN7: The total population of 150,00 individuals was divided into two groups – screening and control. RCC cases and controls were identified from the screening group.] The subjects had baseline serum collected during 1993- 2002, although the samples were not analyzed for PFOA and other PFAS until 2018. The cases were diagnosed with RCC subsequent to serum collection. A control group of 324 individuals who had never had RCC was selected from among the same study participants – matched to the RCC cases by age (>50 years of age), sex, ethnicity, study center, and year of blood draw.

The researchers calculated odds ratios (ORs) for exposure quartiles and for continuous exposure, controlling for multiple potential confounding factors [FN8: These included body mass index, smoking status, hypertension, prior freeze-thaw cycle, year of blood draw, estimated glomerular filtration rate (eGFR), and exposure to other PFAS. Several of these confounders are on their own dose-response continuum, rather than a simple yes/no comparison, which further complicates the ability to pinpoint the effects of PFOA exposure.] in addition to the case-control matching factors. The quartiles were assigned based on serum concentrations of PFOA among controls, resulting in an uneven distribution in the ranges of the quartiles (see Table 1), which can skew the analyses for exposure-response trends. While several potential confounders were evaluated, it is unclear whether the covariates were addressed one at a time (varying each potential confounder, to see how the fit of the model changed) or all at once. No equation is presented in Shearer et al. to help understand their view of the interactions of all the confounders present when assessing the correlations with RCC.

As shown in Table 1 and as emphasized with shading, the data do not support a positive dose-response relationship (Confidence Interval includes 1.0) and would be considered not significantly elevated for the three higher exposure quartiles after adjusting for other PFAS

exposure. The results also do not suggest a dose-response pattern, and the p value for a positive trend was not statistically significant (p=0.13) according to the researchers.

[Table 1: See Docket ID EPA-HQ-OW-2022-0114-1841] [FN10: Continuous OR is in relation to a 1-unit increase in serum PFOA concentration on the log base 2 scale.]

Although the OR for the continuous exposure analysis was statistically significant, questions remain about the meaning of this finding. Of primary concern is whether the single serum measurement taken prior to RCC diagnosis (1993-2002) is representative of exposures over an extended period of time.

Conducting an analysis for continuous exposure, in addition to the quartile analysis, helps to address the disparity in the range of the exposures in the quartiles. However, questions remain about the distribution of exposures between the two groups. Steenland and Winquist point out that serum PFAS concentration contrasts in Shearer et al. study were relatively small, as they reflect general population levels (the lowest PFOA concentration quartile was <4 ng/ml, while the uppermost was >7.3–27.2 ng/ml). [FN11: Steenland K and Winquist A. PFAS and cancer, a scoping review of the epidemiologic evidence. Environ Res 194:110690 (2021).] The supplemental infhttps://academic.oup.com/jnci/article/113/5/580/5906528#supplementary-data] provided by Shearer et al. suggests that the range of serum levels was only slightly higher among the cancer cases compared to the controls, with the exception of a single serum level nearly 10 times the high end of the range in the case group. While this value may explain the use of a log base 2 scale for the continuous analysis, the authors do not explain the potential effect of this outlier on their results. However, the broad confidence interval in the highest exposure quartile suggests that such an explanation is necessary to adequately interpret the findings. Typical publications of this type will generally develop an equation that explains the relationship between the continuous variables, as well as provide a robust uncertainty or sensitivity analysis. These elements are missing from the Shearer et al. publication and would be considered “best practice” for epidemiology that is expected to become the basis for a public health regulation.

Although the researchers were able to use several factors to match controls to the RCC cases, the decision to select an equal number of controls may also limit the significance of the continuous exposure finding. The number of controls selected per case may vary, but it is common in the nested case-control literature to find four or five controls per case. [FN13: Ernster VL. Nest case-control studies. Prevent Med 23(5):94). https://doi.org/10.1006/pmed.1994.1093] The researchers do not provide an explanation for the decision to identify only 324 controls, particularly given the fact that they appear to have had such a large pool of individuals for whom a serum sample had been collected.

Finally, a key topic related to the variety of RCC subtypes that can be diagnosed is the differentiation in tumor type, by genetic basis. An analysis of the subtype of RCC has been a topic of recent interest [FN14: Wang Z et al. Cause-specific mortality among survivors from T1N0M0 renal cell carcinoma: a registry-based cohort study. Frontiers in O21). https://doi.org/10.3389/fonc.2021.604724] due to the variable survival rates and seemingly

different course of both development and treatment. Not all RCC are the same which raises concern that any study linking PFOA to generic RCC could be conflating correlation with causation artificially, by not evaluating by RCC subtype. Analysis of the raw data by subtype may yield a different conclusion, enable a reduction in the statistical uncertainty and also provide clues to where to look in the animal data for subtle mode-of-action data that could clear up the discordance between human and laboratory animal kidney disease attributed to PFOA.

These concerns are echoed by EPA [FN15: USEPA. Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) in Drinking Water. Public Comment Draft. EPA Document No. 822P23005. Office of Water (2023), at 3-265. (USEPA PFOA MCLG Assessment 2023)] which identified deficiencies in controlling for confounding and adequate confidence in selectivity and sensitivity in the study by Shearer et al. Based on "several limitations of the Shearer (2021) study," EPA's Science Advisory Board (SAB) questioned the decision to use its results as the sole basis for the cancer slope factor (CSF). [FN16: USEPA SAB. Review of EPA' Analyses to Support EPA's National Primary Water Rulemaking for PFAS. EPA-SAB- 22-008 (2022), at 38. (USEPA SAB Review)] Because the CSF derived from this study is two to three orders of magnitude more potent than that derived from experimental animal studies, SAB cautioned that "the decision as to what slope factor to recommend needs to be carefully considered and highly transparent." As discussed further below, this concern is compounded by the fact that the EPA's estimate of the benefits of the proposal is based in part on the CSF derived from Shearer et al.

Earlier Epidemiology Studies Provide Conflicting Results

Two other publications explore the incidence of kidney cancer among residents of the Mid- Ohio Valley exposed to PFOA in drinking water – Vieira et al. (2023) [FN17: Vieira VM et al. Perfluorooctanoic acid exposure and cancer outcomes in a contaminated community: a geographic analysis. Environ Health Perspect 121: 318-323 (2013).] and Barry et al. (2013). [FN18: Barry V et al. Perfluorooctanoic acid (PFOA) exposures and incident cancers among adults living near a chemical plant. Environ Health Perspect 121: 1313-1318 (2013).] The study by Barry et al. was conducted in the same study area as Vieira et al. and likely included many of the same participants. However, Barry et al. included information from additional years of follow-up and provides a more recent analysis of cancer incidence in the Mid-Ohio River Valley.

Also, as described in more detail below, Barry et al. includes a more comprehensive assessment of exposure. Moreover, Barry et al. included an analysis of cancer incidence among the workers of the manufacturing facility, whereas the previous study of these workers by Steenland and Woskie (2012) [FN19: Steenland K and Woskie S. Cohort mortality study of workers exposed to perfluorooctanoic acid. Am J Epidemiol 176: 909-917 (2012).] was limited to cancer mortality.

The cohort assembled by Barry et al. included 28,541 residents and 3,713 workers who participated in at least one of the follow-up surveys conducted between 2008 and 2011 and for whom an exposure estimate was available. A total of 105 cases of kidney cancer were identified with a complete data set within the cohort – 87 among the residents and 18 among the workers.

Barry et al. developed estimates of the cumulative PFOA serum concentration using the same model as Vieira et al., but accounted for each participant's reported residential history, drinking water source, tap water consumption, and workplace water consumption. [FN20: Based on measurements taken in 2005-2006, mean serum concentrations were 0.024 mg/L for community residents and 0.113 mg/L for workers.] The researchers calculated hazard ratios (HRs) for an increase in kidney cancer among residents, workers, and the combined group cohort for both continuous and quartiles of PFOA serum concentration. [FN21: The cutoffs for the exposure quartiles are not provided in the publication or supplemental material. The model was adjusted for the same potential confounders as in the analysis by Vieira et al.]

Table 2. Exposure quartiles and continuous log estimated cumulative PFOA serum concentration and risk of kidney cancer risk with a 10-year lag [FN22: Source: Barry et al. 2013 and supplemental materie at https://ehp.niehs.nih.gov/doi/suppl/10.1289/ehp.1306615.]

[Table 2: See Docket ID EPA-HQ-OW-2022-0114-1841]

As a result of the additional follow up, refined exposure assessment, and larger cohort size in the analysis by Barry et al., the association between PFOA exposure and risk of kidney cancer is substantially reduced (See Table 2.) Significantly, the hazard ratio is weakest for workers with a significantly higher median estimated exposure. This finding is consistent with the results of the study by Raleigh et al. who reported no evidence of elevated risk of kidney cancer at a manufacturing facility in Minnesota. [FN23: Raleigh KK et al. Mortality and cancer incidence in ammonium perfluorooctanoate production workers. Occup Environ Med 71:500-506 (2014).] These data raise significant question regarding EPA's decision to rely solely on Shearer et al. for its assessment of RCC risks, as noted by the SAB.

EPA Response: The commenter stated that Shearer (2021) should not have been used to derive a CSF for PFOA. The EPA disagrees that Shearer (2021) was an inappropriate choice for CSF derivation and has provided specific discussion of the commenter's points below. Please also see the EPA response to comment Doc. #1774, SBC-053147 in section 4.2.2.4 in this *Response to Comments* document. The commenter provides two additional studies (Vieira et al., 2013; Barry et al., 2013), suggesting they provide conflicting evidence to Shearer et al. (2021). The EPA disagrees that these studies provide conflicting evidence. As described in the Section 3.5.4 of the final toxicity assessment for PFOA (USEPA, 2024a), a recent critical review and meta-analysis of the epidemiological literature concluded that there was an increased risk for kidney (16 percent) and testicular (3 percent) tumors for every 10 ng/mL increase in serum PFOA (Bartell et al., 2021) (Appendix A, USEPA, 2024a). Although the authors concluded that the associations were likely causal, they noted that there were a limited number of studies and additional studies with larger cohorts could strengthen the conclusion. The recent pooled analysis of the National Cancer Institute (NCI) nested case-control study (Shearer et al., 2021) of 324 cases and controls, and the C8 Science Panel Study (Barry et al., 2013) of 103 cases and 511 controls provided evidence that effects detectable at low exposure are concordant with effects seen in high-exposure studies (Steenland, 2022).

For Shearer (2021), the commenter cites concerns about the use of continuous covariate measurements (e.g., BMI) which they state, "complicates the ability to pinpoint the effects of PFOA exposure." The EPA disagrees that the use of continuous covariates in regression models would negatively impact the ability to determine an effect of PFOA, and the commenter did not provide a citation or reasoning for their assertion. As discussed in section 4.1.2 of this *Response to Comments* document, the EPA followed statutory requirements to use the best available science, including the use of well-established EPA human health risk assessment methodology. As noted in the Potential Confounding domain for study quality evaluation of human studies, "consideration of the most relevant functional forms of potential confounders" was considered a criterion for a Good rating (USEPA, 2024a). The commenter suggests that dichotomization would be the most appropriate choice, however, this practice can commonly lead to additional residual confounding for continuous covariates such as BMI or eGFR by ignoring or obfuscating more complicated relationships between the confounder and outcome of interest (Groenwold, 2013). Additionally, the commenter raises issue with the fact that "no equation is presented" by Shearer et al. (2021) which demonstrates their understanding of interactions of all confounders in the analysis of RCC; however, the EPA disagrees that this is a critical flow for control for potential confounding. Presentation of an "equation" is not required nor is it considered in the evaluation of Potential Confounding (USEPA, 2024a).

The commenter raises concerns about lack of statistical significance in quartile analyses in Shearer et al. (2021). The EPA disagrees that the non-significant results from quartile analyses make the study inappropriate for CSF derivation. Results from quartile analyses, while not significant, were consistent with the continuous analysis. Statistical significance is not the sole factor when making evidence synthesis judgements, and results that lacks statistical significance can be used to support a conclusion of an effect (Wasserstein and Lazar, 2016; USEPA, 2022a).

The two studies (Vieira et al., 2013; Barry et al., 2013) provided by the commenter both examine the incidence of kidney cancer in the C8 Health Project Community. The commenter incorrectly suggests these studies provide conflicting evidence of an association between elevated exposure to PFOA and incidence of kidney cancer. Risk estimates from both studies were positive, indicating an increased risk of kidney cancer which does not conflict with the results of Shearer et al. (2021). The commenter points to a stratified analysis reported in Barry et al. (2013) which provides a null association for the risk of kidney cancer in an occupational sub-population. However, the commenter did not address the smaller number of cases when stratifying by occupational status, which would decrease the sensitivity of that particular analysis. Importantly, both studies provided by the commenter analyze kidney cancer without distinction of histological subtype. Shearer et al. (2021) analyzes renal cell carcinoma, which may be a more sensitive indicator. An additional study identified after the updated literature search has identified increased risk of renal cell carcinoma in the American Cancer Society's prospective Cancer Prevention Study II (Winquist et al., 2023).

The commenter provides other incorrect assertions about Shearer et al. (2021), including that the assignment of exposure quartiles based on serum PFOA concentrations in controls would skew

the analyses for exposure-response trends, whether the single PFOA measurement was appropriate for analyzing risk of RCC, and consistency with prior epidemiological evidence. The EPA disagrees with these assertions, and further discussion of these issues can be found in the EPA response to comment Doc. #1774, SBC-053147 in section 4.2.2.4 in this *Response to Comments* document. The commenter additionally states that the EPA did not implement SAB feedback on the use of Shearer et al. (2021) for the derivation of a CSF. The EPA disagrees SAB feedback was not implemented, and further discussion of the EPA response to the SAB can be found in section 4.1.3 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1774, SBC-045682 and Doc. #1774, SBC-045683 in section 4.1.4.3 in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-052920)

The CSF for PFOS relies on animal evidence for liver effects that may have little relevance to humans.

EPA Response: Please see the EPA response to comment Doc. #1774, SBC-053190 in section 4.1.4.2 in this *Response to Comments* document and section 4.1.4 of the EPA response in this *Response to Comments* document.

4.2.3 Characterization of Hazards for Non-Priority Health Outcomes

Mike Pettit (Doc. #1542, SBC-052840)

Endocrine effects: page 269 reads "There is suggestive evidence of a positive association between PFOA/PFOS exposure and thyroid hormone disruption. Epidemiology studies reported inconsistent evidence regarding associations between PFOA or PFOS exposure and general endocrine outcomes, such as thyroid disease, hypothyroidism, and hypothyroxinemia. However, studies reported suggestive evidence of positive associations for thyroid stimulating hormone (TSH) in adults, and the thyroid hormone thyroxine (T4) in children. Toxicology studies indicated that PFOA and PFOS exposure leads to decreases in thyroid hormone levels and adverse effects to the endocrine system. Despite uncertainty around the applicability of animal studies in this area, changes in thyroid hormone levels in animals did indicate adverse effects after PFOS and PFOA exposure that is relevant to humans."

Once again, there it exists the problem that there are serious inconsistencies within the studies and the results being produced. Thyroid pathways are very well documented and as such the interfering mechanisms should be decently simple to pinpoint and yet that pinpoint accuracy seems to be lacking. The results are inconsistent at best, and should be treated as such.

Metabolic effects: page 270 reads "Evidence suggests a direct association between PFOA exposure and leptin levels in the general adult population. Based on a review of 69 human epidemiology studies, evidence of associations between PFOS and metabolic outcomes appears

inconsistent, but in some studies, suggestive evidence was observed between PFOS exposure and leptin levels."

As some studies have reported a positive association between PFOS exposure and metabolic outcomes such as insulin resistance, dyslipidemia, and obesity, others have found no significant association. This inconsistency in results may be due to differences in study design, sample size, and population characteristics, among other factors. Also while cross-sectional and observational studies can provide useful information on the association between PFOS exposure and metabolic outcomes, they cannot establish causality. Randomized controlled trials, which are considered the gold standard for establishing causality, are not always feasible or ethical when studying environmental exposures. It is also important to consider the potential for reverse causation. Metabolic dysfunction may alter the way the body metabolizes and eliminates PFOS, leading to higher levels of PFOS in the body. Therefore, the observed association between PFOS exposure and metabolic dysfunction may actually be due to metabolic dysfunction leading to higher PFOS levels, rather than the other way around.

Reproductive effects: page 271 reads "The epidemiology evidence yields mixed (positive and nonsignificant) associations, with some suggestive evidence supporting positive associations between PFOA/PFOS exposure and both preeclampsia and gestational hypertension."

Firstly, many studies have focused on animal models, and there are significant differences in the way that PFOS affects animal and human reproductive systems. While animal studies can provide valuable insights into the potential effects of PFOS, it can be difficult to extrapolate these findings to humans. Of second note, many studies on human populations have relied on self-reported data or retrospective analyses, which can be subject to bias and inaccuracies. Additionally, many studies have relied on small sample sizes, making it difficult to draw firm conclusions about the potential reproductive effects of PFOS.

Musculoskeletal effects: page 271 reads "There is limited evidence from studies pointing to effects of PFOS on skeletal size (height), lean body mass, and osteoarthritis. Some studies found that PFOA/PFOS exposure was linked to osteoarthritis, in particular among women under 50 years of age. However, other reviews reported mixed findings on the effects of PFOS exposure including decreased risk of osteoarthritis, increased risk for some demographic subgroups, or no association."

There is limited evidence linking PFOS exposure to musculoskeletal effects, which can make it difficult to draw definitive conclusions about this association. Some studies have suggested that PFOS exposure may be associated with decreased bone density and an increased risk of bone fractures, particularly in older adults. Again however, other studies have not found a significant association between PFOS exposure and musculoskeletal outcomes. Studies on this association are relatively scarce, which can make it challenging to draw definitive conclusions about the effects of PFOS exposure on musculoskeletal health. Additionally, many studies have relied on self-reported outcomes, which may not be accurate or reliable indicators of actual musculoskeletal health.

EPA Response: The commenter raised concerns about several non-priority health outcomes (i.e., endocrine effects, metabolic effects, reproductive effects, and musculoskeletal effects), noting various perceived inconsistencies in the human and animal evidence. The EPA disagrees that these health outcomes were inappropriately synthesized. The evidence integration judgement for each of these outcomes noted that the *evidence suggests* adverse effects from elevated exposure to PFOA and PFOS, and the EPA identified uncertainties that led to these conclusions, including the quotes provided by the commenter (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b). An evidence integration judgement of "*evidence suggests"* is typically made with a combination of *slight* or *indeterminate* evidence stream judgments for animal and human evidence (USEPA, 2022a, Table 6-7). The human evidence stream judgement for each outcome was considered *slight*, and the quotes and descriptions provided by the commenter do not deviate from the descriptions provided in the IRIS Handbook (USEPA, 2022a). For human evidence, a *slight* evidence stream judgment may be made when "one or more studies report an association between exposure and the health outcome, but considerable uncertainty exists" (USEPA, 2022a, Table 6-4). Additional research may provide further clarity regarding the effects of PFOA and PFOS on each health outcome, however, the health outcomes considered to have an "*evidence suggests"* evidence integration judgement were not considered for dose-response analyses and RfD derivation in the PFOA and PFOS toxicity assessments (USEPA, 2024d; USEPA, 2024c). Concerns regarding these health outcomes do not impact the EPA's conclusion that PFOA and PFOS are *Likely to be Carcinogenic to Humans* and the resulting MCLGs of zero (USEPA, 2024e).

4.2.4 Pharmacokinetic Modeling Approach

Washington State Department of Health (DOH) (Doc. #1665, SBC-052885)

DOH also appreciate that EPA added the modified Verner model to account for transplacental and trans-lactational exposure in developing children.

EPA Response: This commenter supports the approach used in the EPA's draft and final toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a; USEPA, 2024d; USEPA, 2024c).

3M Company (Doc. #1774, SBC-053233)

f. EPA Did Not Follow SAB Recommendations to Address Lack of Transparency, Lack of Reproducibility, and High Levels of Uncertainty in its Use of PBPK Models

PBPK models were used to simulate dosimetry during pregnancy and lactation for endpoints in human neonates and children. The SAB considered EPA's use of compartment based PBPK models to be reasonable but requested that details and assumptions required to run the model be documented sufficiently to allow reproduction of the simulations. EPA failed to address SAB comments regarding clarity of the PBPK model and EPA's lack of evaluation of the PBPK model

performance. EPA placed the PBPK model code on Github to allow reproduction of simulations but failed to provide sufficient documentation or a required header file ('linear_interp.h') needed to compile and run the code. As a result, the conversion of the point of departure (POD) to the POD human equivalent dose (PODHED) could not be reproduced and remains uncertain. These issues are discussed below and in detail in Appendix A.

From Appendix A: EPA did not provide required files or sufficient documentation to reproduce the conversion of the PODs to the PODHEDs.

The SAB recommend that EPA provide more details on model code, parameters, data and performance. In response, EPA posted the model code and supporting documentation on GitHub. As provided, users could not validate the code and the parameters because EPA failed to provide a required header file ('linear_interp.h') needed to compile and run the code. This means the public cannot assess data and performance. This, in turn, prevents the public from meaningfully commenting on EPA's approach.

EPA Response: The commenter noted that they were unable to download and run the code supporting the PK model. The commenter incorrectly concluded that the EPA failed to provide a required header file. Prior to rule proposal (March 14, 2023), the EPA ensured that the code was publicly available and usable by the public and could be accessed by following the instructions provided on the GitHub site by conducting two internal independent confirmations. The EPA has since confirmed that every required piece of code is available in the GitHub repository. The EPA did not write C code or headers that would require a file of the type "linear_interp.h" that would be necessary for the code to function; thus, the EPA did not fail to provide a file of this type as it is not needed. To ensure external stakeholders can effectively use the code, the EPA has since conducted a third independent test and found that individuals outside the EPA can access, download, and run the code. The EPA recognizes that software packages are frequently updated and may result in user error that would not be identified during internal QC. This is why the EPA explicitly stated in the "readme" file found in the GitHub repository, "if you need help with installing or executing the code, please contact us through a Github issue." The EPA did not receive issues reported to the repository during the public comment period and therefore was unable to assist the commenter. In short, the commenter's inability to correctly download and use the model and their decision not to contact the readily available Github contact and resource to remedy their technological issues did not result from an error by the agency. Additionally, the EPA has conducted a full review of the model code and performed minor modifications to improve compatibility on a wider variety of system configurations. These modifications are logged as comments in the GitHub repository.

3M Company (Doc. #1774, SBC-053237)

i. EPA failed to adequately perform sensitivity analysis for PBPK modeling and provide a quantitative assessment of model performance.

EPA also failed to address SAB's recommendation that EPA better characterize the uncertainty that results from different parameters/assumptions by considering sensitivity analyses or Monte Carlo simulations with a range or distribution of values. EPA did not perform a quantitative assessment of model performance and, as such, failed to address SAB's comment. Best practice frameworks recommend the use of global and local sensitivity analysis (Johnson et al. 2021). EPA only performed local one-at-a-time sensitivity analysis. The parameter(s) driving the output value (i.e., intake-based HED derived from a serum measurement) were not identified and sufficient quantification was not provided in EPA's one-at-a-time sensitivity analysis to fully assess the overall relative importance of all model parameters. This issue is discussed in detail in Appendix A.

From Appendix A:

The SAB stated EPA needs to better characterize the uncertainty caused by different parameters/assumptions by considering sensitivity analyses or Monte Carlo simulations with a range or distribution of values. This is consistent with best practice frameworks, which recommend the use of global and local sensitivity analysis (Johnson et al. 2021). EPA failed to address this comment because the agency did not perform a quantitative assessment of model performance. EPA only performed a single, local, one-at-a-time sensitivity analysis that failed to examine the interaction of model parameters. A global sensitivity analysis would consider those interactions and provide the agency with a better overall understanding of the impact of uncertainty factors on its conclusions.

Additionally, EPA did not identify the parameter(s) driving the output value (i.e., intake based HED derived from a serum measurement). EPA did not provide sufficient quantification in its one-at-a-time sensitivity analysis to fully assess the overall importance of all model parameters and adequately address SAB comments.

EPA used results from its one-at-a-time sensitivity analysis to identify the chemical specific parameters of Vd (volume of distribution) and half-life as sensitive parameters that influence serum and cord blood concentrations of PFOA or PFOS. However, the ranges chosen run contrary to those suggested by the best available science. Available literature provides ranges for both the Vd and half-life which would be more appropriate to consider than the mean values used by EPA. EPA compiled such ranges in values in its draft toxicity assessment Appendices for PFOA and PFOS. Notably, the mean half-lives for PFOA and PFOS used by EPA (i.e., 2.7 and 3.4 yrs, respectively) were from Li et al. (2018). The same Li et al. publication provided a 95% confidence interval for the half-life for both PFOA and PFOS (i.e., 2.5-2.9 and 3.1-3.7 yrs for PFOA and PFOS, respectively), which may be more appropriate to use as input values for half-life. Similarly, the Vd for PFOA and PFOS have been derived by a number of different

publications, whereas EPA used a single value from Thompson et al. (2010) (i.e., PFOA = 170 ml/kg and PFOS = 230 ml/kg). Within the draft Appendix for PFOA, for example, Table B-26 notes 10 values for Vd from 7 publications that range from 170-200 ml/kg.

The reported ranges for Vd and half-life could have a substantial impact on the subsequent PODHED value, which affects EPA's ultimate conclusions. In addition, the cord blood:maternal serum ratio parameter was also identified as a sensitive parameter. EPA used an average cord blood:maternal serum ratio estimated from values available in the peer-reviewed literature for PFOA and PFOS; however, the 95% confidence interval for PFOA values available in the peer-reviewed literature is 0.5819-1.441. The effect of the variability in the values for this sensitive parameter on PFOA and PFOS serum levels in children should be quantified in order to assess the appropriateness of the average value used for PBPK modeling.

EPA Response: The commenter stated that the EPA failed to address SAB's recommendation to better characterize uncertainty in the pharmacokinetic modeling approach. First, please see section 4.1.3 of the EPA response in this *Response to Comments* document and the EPA response to SAB comments document (USEPA, 2023d). The commenter also recommended a global sensitivity analysis (GSA) as an approach to meet the SAB's recommendation. The EPA disagrees with these claims. As noted by the commenter, the SAB recommended that the EPA perform sensitivity analyses *or* Monte Carlo simulations; as recommended by the SAB, the EPA performed those sensitivity analyses and the results were provided in Appendix F of the toxicity assessments for PFOA and PFOS at the time of rule proposal (USEPA, 2023b; USEPA, 2023c), thus addressing this recommendation. The EPA decided to conduct local sensitivity analyses because they are sufficient to understand how uncertainty in the parameters propagates to the model output for the PK approach used in these assessments. The EPA disagrees that a GSA approach is a better option for these analyses. If the EPA had used a full PBPK model approach, with a complex structure and parameter interaction that can often be unpredictable, then GSA could be an appropriate alternative approach to understand how simultaneous variation in parameters affect the model. In fact, this sentiment is supported by Johnson et al. (2021), which state that best practices "for any uncertain parameters within the pediatric PBPK model perform sensitivity analysis if they are likely to have a significant impact" are to conduct "global *and/or* local sensitivity analysis within PBPK platform" (emphasis added). However, for the EPA's PK modelling approach used to inform the toxicity assessments, use of the GSA adds unnecessary complexity and would not meaningfully address the variation in parameters used in the model. Regarding parameters that drive the output, the local sensitivity analyses conducted by the EPA will return the same results whether the model is run forwards (i.e., from serum measurement to human equivalence dose) as backwards (i.e., from human equivalence dose to serum measurement). Therefore, the local sensitivity analyses already "identify the parameter(s) driving the output value" and further GSAs are not needed.

The commenter raises concerns with values the EPA used for the PFOA and PFOS half-life, volume of distribution (Vd), and cord blood to maternal serum ratio (RCM) variables. The

commenter did not provide references supporting the claim that the EPA did not select values for Vd and half-life that reflect the best available science, nor did the commenter provide a recommendation for alternative values from the literature to consider instead of half-lives from Li et al. (2018), Vd estimates from Thompson et al. (2010), and a ratio of cord blood to maternal blood concentrations (RCM) based on average of values reported in the literature as was done in the original publication Verner et al. (2016). Additionally, the commenter recommends that the EPA use a 95% CI as the input for the RCM and half-life parameters. This approach is not statistically defensible and misinterprets the meaning of a CI. A CI is a range of values for which there is a specified probability that the true value of the parameter lies within it. In this modeling context, it is not intended to serve as a representation of the range of values for a population. As the commenter did not provide new information or a valid approach for the EPA to consider, the EPA has maintained the selected values for half-life, Vd, and RCM in the pharmacokinetic modeling approach for PFOA and PFOS.

3M Company (Doc. #1774, SBC-053238)

ii. EPA did not follow SAB's recommendation to use the Goeden et al. (2019) model as a more 'fit for purpose' model for deriving MCLGs

SAB recommended that EPA consider its use of the Verner et al. (2016) models and whether the Goeden et al. (2019) model that incorporates age-specific toxicokinetic and exposure factors would be more appropriate for deriving drinking water MCLGs. EPA compared use of the Verner and Goeden models and concluded that there was no "substantial improvement" in the outcome when modeled using either method. This statement was not supported by a side-by side comparison of results or sufficient information to allow for assessment and an understanding of whether the appropriate model was selected. Data should be presented to support how the decision to use constant daily dose versus age-specific toxicokinetic factors (e.g., volume of distribution) and exposure factors (milk and drinking water intake) affects the model outcome. This issue is discussed in detail in Appendix A.

From Appendix A: EPA did not follow the SAB recommendation to consider age-specific toxicokinetic and exposure factors and use the Goeden et al. (2019) model, which SAB said is more "fit for purpose" for deriving drinking water MCLGs. The Goeden model used an age-dependent adjustment for the volume of distribution (Vd) parameter instead of the constant Vd used by EPA. The SAB noted that the Goeden et al. (2019) appeared to have equal or better model fits as compared to the Verner et al. (2016) model.

EPA did not follow SAB's recommendation and instead asserted that there was no "substantial improvement" in the outcome when modeled using either method. However, EPA provided no side-by-side comparison or additional information to justify its selection of the Verner model. To improve transparency, EPA should provide quantification of the evidence to support the selection of a constant value for Vd parameters and the Verner model.

EPA Response: The commenter stated that the EPA did not follow the SAB PFAS Review Panel's recommendation to use the Goeden et al. (2019) model and did not provide quantitative comparisons or additional information to justify its selection of the Verner et al. (2016) model. The commenter is incorrect in stating that the SAB recommended the EPA "use" the Goeden et al. (2019) model instead of the Verner et al. (2016) model; in actuality, the SAB PFAS panel asked the EPA to "consider whether the Goeden et al. (2019) model is more appropriate for use in development of the PFOA and PFOS RfDs and MCLGs" (USEPA, 2022b). The EPA provided extensive rationale and quantitative discussion for the decision not to use the Goeden et al. (2019) model as the basis of the PK model in both the response to SAB comments document (USEPA, 2023d), the final toxicity assessments (see Section 5.7; USEPA, 2024d; USEPA, 2024c) and associated appendices (see Appendix F.2 for quantitative considerations; USEPA, 2024a; USEPA, 2024b).

Regarding the commenter's concern about the Vd parameter, the EPA provided a quantitative comparison of incorporation of the Vd from the Goeden et al. (2019) model with a constant Vd and determined that "[b]ased on mean relative error (for PFOA and PFOS combined) the model with constant Vd had better performance" (Appendix F.2; USEPA, 2023b; USEPA, 2023c). The EPA expanded the quantitative comparison with the addition of root mean square error (RMSE) in Appendix F.2 to address this concern (USEPA, 2024a; USEPA, 2024b). This additional comparison further supported the better fit to validation data using a model with a constant Vd. Rationale for the EPA's selection of the Verner et al. (2016) model, provided at the time of rule proposal, is available in Section 4.1.3 of the final toxicity assessments (USEPA, 2024d; USEPA, 2024c). Documentation of the evaluation of the Goeden et al. (2019) model for its use in these assessments is provided in Section 5 ("Human Dosimetry Models: Consideration of Alternate Modeling Approaches") and Appendix F.2 of the final toxicity assessments and Section I, Charge Question #4 in the EPA Response to Final Science Advisory Board Recommendations document (USEPA, 2023d; USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

3M Company (Doc. #1774, SBC-053240)

iii. EPA failed to account for life stage-specific variables in the PBPK model that impact the resulting PODHED

The PBPK model used by EPA does not account for life stage (maternal, fetal, infant) differences in parameters such as elimination and clearance rate, half-life, and volume of distribution (Vd), as recommended by the SAB. To clarify the uncertainty in life stage-specific variables, age-related differences in chemical-specific parameters should be considered to better explain the variability observed (i.e., lack of fit) in predicted child serum levels compared to reported child serum levels of PFOA and PFOS (see Figures F-15 and F-12 in draft Appendices for PFOA and PFOS, respectively). Consideration of life stage-specific variables may also impact the resulting PODHED. This issue is discussed in detail in Appendix A.

From Appendix A: The SAB recommended that model performance be documented for different life stages. However, the PBPK model EPA used failed to account for life stage (maternal, fetal, infant) differences in parameters such as elimination and clearance rate, half-life, and volume of distribution (Vd). To clarify the uncertainty in life stage-specific variables, EPA should consider age-related differences in chemical-specific parameters to better explain the variability observed (i.e., lack of fit) in predicted child serum levels compared to reported child serum levels of PFOA and PFOS (see Figures F-15 and F-12 in draft MCLG Appendices for PFOA and PFOS, respectively).

In addition, the PBPK model code (GitHub) has the functionality to allow the input values for these parameters to vary. Despite this, EPA's only uses an adult clearance rate value. The elimination rate, derived from clearance rate, is similarly a static value. EPA did not use the model functionality that allows clearance rate to be adjusted for the specific life stage (listed below) being modeled or provide information on the model variability that would occur with the use of life stage-specific values.

· 0 – 12.4y: Childhood / Pre-pubertal

· 12.4y – 24.25y: Puberty / Menstruation begins

· 24.25y – 26y: Pregnancy and breast feeding

· 26y – 50y: Adulthood / Menstruation

Therefore, the PBPK model used by EPA fails to capture sources of variability introduced by life stage as recommended by SAB.

EPA Response: The commenter stated that the PBPK model the EPA used did not account for lifestage differences in model parameters and recommended that the EPA consider age-related differences to explain the variability in predicted child serum levels compared to reported child serum levels for the literature. First, the commenter incorrectly described the approach used in the toxicity assessments for PFOA and PFOS, which was not a full PBPK model approach, but a PK model approach (see section 4.1.3; USEPA, 2024d; USEPA, 2024c). Further, upon review of the available literature, the EPA determined that the available data were too limited to inform lifestage-specific values (see descriptions of the available literature in Appendix B and human model validation Appendix F.3; USEPA, 2024a; USEPA, 2024b). The commenter did not provide any data or references to inform lifestage-specific values that contradict this finding. The EPA also did not identify data to inform clearance specific to children and therefore used the available data for total clearance for the general population as the model parameter. Additionally, the logic in the code is intended to turn on and off menstrual clearance coincident with puberty, pregnancy, and the end of lactation. The EPA's selected half-life value is derived from the observation of decreasing blood levels over time, which result in a measurement of total clearance, as opposed to data informing urinary clearance, to which menstrual clearance could or could not be added. Since the applied clearance value is from the general population it captures clearance from all sources. Further, adding ad hoc adjustments for

predictions of how clearance might change during childhood and pregnancy and/or lactation that is not based on available data would increase uncertainty in this case.

The EPA disagrees with the commenter's statement that there is a lack of fit in predicted and observed child serum levels. This is shown in the EPA's model validation discussions and analyses available in Appendix F (USEPA, 2024a; USEPA, 2024b). Briefly, for PK modeling, a common criterion for model validation are predictions within a factor of two of the validation data (Sager, et al. 2015). The models clearly fit all the validation data well within a factor of two. The EPA added guidance lines to the figure of predicted versus observed serum concentration to highlight the excellent fit of the model to the validation dataset in children. For additional proof of validation, the EPA added a table of root mean squared error (RMSE) values for the assessment model compared to the alternative models presented in Appendix F and discussed in Section 5.7 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b).

3M Company (Doc. #1774, SBC-053454)

Within the Effects Characterization section of the EPA draft toxicity assessments for PFOA and PFOS, EPA provides a qualitative uncertainty assessment for some of the chemical specific model parameters selected for PBPK modeling, including clearance rate, volume of distribution, and half-life. In addition, EPA discusses its consideration of alternate modeling approaches. However, despite SAB's recommendation to do so, a quantitative evaluation of model performance was not conducted by EPA; therefore, uncertainties in the resulting HED estimations were also not assessed by EPA.

EPA Response: The commenter incorrectly states that the EPA did not quantitatively evaluate the pharmacokinetic model performance and therefore, did not assess uncertainty in human equivalence dose estimations. The commenter is correct in stating that qualitative evaluations of model performance are described in the Effects Characterization section of the toxicity assessments (Section 6 of the public comment draft (USEPA, 2023f; USEPA, 2023a); now section 5 of the final toxicity assessments (USEPA, 2024d; USEPA, 2024c)), but the EPA also provides quantitative validations of both the animal and human pharmacokinetic models in Appendix F (USEPA, 2023b; USEPA, 2023c; USEPA, 2024a; USEPA, 2024b). Specifically, the EPA presented mean square log error (MSLE) analyses for both the training and test sets to evaluate animal model performance (see Figures F-4 and F-12 of USEPA, 2023b; USEPA, 2023c). Both the training and test data showed good agreement with model predictions using the male-specific parameters from Wambaugh et al. (2013), with MSLE for the adult training datasets and developmental test datasets under a half-$\log_{10}$ and about one $\log_{10}$ for the adult test datasets. Because experimental serum concentrations spanned many orders of magnitude, the EPA presented the unity line with +/- half-$\log_{10}$ to visualize the goodness of fit. The results of these analyses indicate that there were no systematic differences between the experimental data and the model predictions across species, strain, or sex, and the median model outputs uniformly appeared to be biologically plausible despite the uncertainty reflected in some of the 95th

percentile CIs. In general, the internal dose metrics used in these analyses were not sensitive to the parameters with the largest credible intervals following the Bayesian inference calibration. In other words, the results of the sensitivity analyses demonstrated that changing the most uncertain parameters from the modified Wambaugh et al. (2013) model did not impact the internal dose metrics.

For the human model, the model predictions shown in Figure F-12 of the draft assessments show the good qualitative fit of the model compared to the alternatives shown in Figures F-15 and F-16 (USEPA, 2023b; USEPA, 2023c). The EPA has addressed this comment by adding results of root mean squared error (RMSE) analyses for the human model to the assessments (see Appendix F; USEPA, 2024a; USEPA, 2024b). The results of this analysis quantitatively show that the EPA's model with the selected parameters performs better than other alternatives.

3M Company (Doc. #1774, SBC-053243)

iv. EPA failed to quantitatively characterize uncertainty for PBPK modeling and HED calculations

Monte Carlo simulations recommended by the SAB were not performed by EPA for PBPK modeling of co-critical endpoints including vaccine response and birth weight to inform the variability inherent in the modeling approach. In addition, the variability of chemical-specific parameters used to calculate the HED for total cholesterol was not quantified by EPA. Therefore, range of uncertainty in the resulting PODHED estimations were also not considered by EPA. This issue is discussed in detail in Appendix A.

From Appendix A: EPA did not thoroughly describe and quantify the uncertainty in each of the parameters used in the PBPK models or HED calculations. EPA did not perform Monte Carlo simulations recommended by the SAB for PBPK modeling of co-critical endpoints including vaccine response and birth weight to inform the variability inherent in the modeling approach and to provide a range of distribution of PODHED values. In addition, uncertainty in the HED used by EPA for total cholesterol was not evaluated. EPA did not provide a description or quantification of the variability in the chemical-specific parameters used to calculate the HED for total cholesterol. An understanding of the underlying variability in these parameters will inform the overall uncertainty in the resultant HED value for total cholesterol.

EPA Response: The commenter states that the EPA did not perform Monte Carlo simulations to evaluate uncertainty in each of the parameters. The SAB panel recommended the EPA consider sensitivity analyses *or* Monte Carlo simulations. The EPA elected to assess the model dependence on uncertainty and variability on individual parameters by performing local sensitivity analyses, the results of which are described in previous responses. Additionally, Monte Carlo simulation wouldn't increase our knowledge regarding model uncertainty because only parameter variability can be accounted for in this type of analysis, not model uncertainty. Monte Carlo simulation will only tell us population variability which is not useful if you want to know the central tendency of the distribution. In this case, the sensitivity analyses serve the same

purpose as the Monte Carlo simulations. This approach is fully consistent with the SAB recommendations.

The commenter also suggests providing a range of distribution of POD_{HED} values. The EPA disagrees with this approach, which has not been historically used by the agency in chemical assessments. In general, it is best to present one HED per endpoint that represents the best estimate of the POD_{HED}; providing a distribution of POD_{HED} estimates would potentially increase the uncertainty in the value as the EPA would likely consider using a measure of central tendency or similar as the overall POD_{HED} rather than selecting the most scientifically sound POD_{HED} as the EPA does in Section 4 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c).

Lastly, the commenter incorrectly states that the EPA did not evaluate or provide description of the variability in parameters used to calculate the HED for total cholesterol. The parameters used in the PK models to derive POD_{HED}s for total cholesterol are the same as those used to derive POD_{HED}s for all other health outcomes. Uncertainties in the selected approach, including uncertainty related to variability in the parameters used in the PK model are described in Sections 4.1.3.2 and 5.6.2 and Appendix F of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c; USEPA, 2024a; USEPA, 2024b). Calculation of the POD_{HED} for total cholesterol is described in section 4.1.4.3 of the final toxicity assessments (USEPA, 2024d; USEPA, 2024c).

Anonymous (Doc. #2331, SBC-047414)

There has not been a large enough database of information on the levels in people's blood or liver over time to make statements that these chemicals accumulate in the body over time. New data is just lies from a politically motivated unconstitutional government bureaucracy. There is no proof that removing PFAS from drinking water will reduce cancer or any other health issues, it is all just modeling and extrapolation being pushed on us as facts.

Our organization has been treating water for potable use for over 40 years. This is an egregious leap into trying to make a problem and health concern where there is none.

EPA Response: The commenter is incorrect that there is not a database to demonstrate that PFAS accumulate in the body over time. The EPA directs the commenter to the Center for Disease Control's National Health and Nutrition Examination Survey (NHANES) website for decades of biomonitoring data confirming the presence of PFAS in human biological samples from the U.S. population (https://www.cdc.gov/nchs/nhanes/index.htm). Regarding potential biases, please see section 4.1.2 of the EPA response in this *Response to Comments* document. Please refer to the Final Regulatory Determination for PFOA and PFOS (USEPA, 2021f), section III of this rule and section 3 of this *Response to Comments* document for the EPA's rationale supporting the conclusion that regulating these compounds presents a meaningful opportunity for health risk reduction. The commenter provides no information to support their statement that "New data is just lies from a politically motivated unconstitutional government bureaucracy."

However, a substantial portion of the supporting information used to inform this rulemaking and these toxicity assessments were collected and analyzed by nongovernmental sources. Additionally, fabrication of data is a violation of the EPA's scientific integrity policy: it was not done here as falsely asserted by commenter with no evidence or information to support their unfounded, unwarranted, and misinformed claim.

4.2.5 Relative Source Contribution (RSC)

Summary of Major Public Comments and EPA Responses

Many commenters misunderstand the EPA's derivation of relative source contributions (RSCs) for the 6 PFAS covered under this rulemaking. Many commenters misinterpret the EPA's RSC determinations, incorrectly citing the 20 percent RSCs or the 80 percent of exposure expected to occur as a result of exposure to other sources out of context of the RfDs, HBWCs, Health Reference Levels (HRLs), or MCLGs. The RSC terms are derived for a specific purpose and are meant to be applied to the RfD. Specifically, the RSC is the "percentage of total exposure typically accounted for by the exposure source for which the criterion is being determined… [and] is applied to the RfD to determine the maximum amount of the RfD "apportioned" to that source" (USEPA, 2000c). As stated by the SAB PFAS Review Panel, "The RSC determination should not be based on the relative PFOA or PFOS water to non-water exposures, without the context of the RfD" and "the choice of the RSC depends on the numerical value of the RfD" (USEPA, 2022b). Therefore, comparisons made by commenters to the RSCs derived by other agencies (e.g., state health agencies) may only be relevant if those agencies used the same RfDs as the EPA. Similarly, comparisons of the RSCs to publications that attempt to quantify exposure without context of the RfD, the target population of interest, and policy considerations of the Exposure Decision Tree approach outlined by the *EPA Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (USEPA, 2000c) are not relevant and often are in direct contradiction to this peer-reviewed RSC methodology.

The Exposure Decision Tree approach considers several characteristics of the contaminant of interest, including the adequacy of available exposure data, levels of the contaminant in relevant sources or media of exposure, and regulatory agendas (i.e., whether there are multiple health-based criteria or regulatory standards for the contaminant). The EPA describes the data and decisions made to determine the RSCs for PFOA, PFOS, PFNA, PFHxS, HFPO-DA, and PFBS and walks through the Exposure Decision Tree for each chemical in the RSC Determination sections found across several supporting documents published at the time of this rulemaking (USEPA, 2024a; USEPA, 2024b; USEPA, 2024h). Several factors considered during this process are described further below as they relate to some of the public comments the EPA received on the proposed PFAS NPDWR.

Although the RSC may be entirely science-based in cases when the agency has the data required to conduct this "apportionment," frequently, as was the case for all 6 PFAS considered under this rulemaking, the agency must rely on risk policy factors outlined by the Exposure Decision Tree approach to determine the RSC (USEPA, 2000c). One example risk policy decision that is

described later in this response and is impactful for this rulemaking is the application of an 80 percent ceiling and 20 percent floor for the RSC. A quantitative RSC determination first requires "data for the chemical in question… representative of each source/medium of exposure and… relevant to the identified population(s)" (USEPA, 2000c). The term "data" is defined as ambient sampling measurements in the media of exposure, not internal human biomonitoring metrics. More specifically, the data must adequately characterize exposure distributions including the central tendency and high-end exposure levels for each source and 95% CIs for these terms. The 2000 *Methodology* additionally outlines factors to consider when determining whether a dataset is "adequate" (USEPA, 2000c). Notably, "monitoring study reports often fail to include background information or sufficient summary statistics (and rarely the raw data) to completely characterize data adequacy" (USEPA, 2000c).

The RSC determinations for PFOA, PFOS, PFNA, PFHxS, HFPO-DA, and PFBS are complex in that there is evidence supporting the occurrence of these 6 PFAS in numerous exposure media, which may result in potentially significant contributions to total exposure by media other than drinking water (USEPA, 2024a; USEPA, 2024b; USEPA, 2024h). A quantitative RSC derivation would therefore require adequate monitoring data for all of the potentially significant sources of exposure (USEPA, 2000c). The EPA presents the available monitoring data showing the presence of the 6 PFAS in environmental media including food, indoor and outdoor air, house dust, consumer products, and others (USEPA, 2024a; USEPA, 2024b; USEPA, 2024h). Many of the studies provide evidence of exposure and occurrence but are specific to certain locations and therefore may not be generalizable to the U.S. population as a whole or more specifically to the identified population(s) of concern. Other studies are limited in terms of data adequacy. For example, some studies present monitoring data in only a small number of products or samples and others do not present raw data. Data were even more limited when the agency specified monitoring relevant to susceptible populations such as infants, children, and pregnant individuals. Therefore, for all 6 PFAS, the agency determined that the data were inadequate to quantitatively derive the RSC (USEPA, 2024a; USEPA, 2024b; USEPA, 2024c). Additionally, commenters did not provide information that would allow the EPA to quantitatively derive the RSCs for any of the six PFAS included in this rulemaking.

When adequate quantitative data are not available, the agency relies on the qualitative alternatives of the Exposure Decision Tree approach. A "qualitative alternative" RSC is not based on monitoring data and therefore, the selected RSC is not necessarily the actual percent of contaminant exposure that the EPA expects to result from an exposure source or medium of concern. In reality, a qualitative RSC is an estimate that incorporates data and policy considerations and thus, is sometimes referred to as a "default" RSC (USEPA, 2000c). Many commenters misinterpreted the EPA's qualitative RSCs as conclusions about actual contribution of drinking water exposure to total exposure. To reiterate, references to the 20 percent allocation to drinking water or 80 percent allocation to other sources/media without the context of the RfD and policy considerations of the 2000 Methodology (USEPA, 2000c) are incorrect applications of the RSC and incorrect interpretations of the agency's conclusions about PFAS exposure.

As described in the *Methodology*, "The underlying objective is to maintain total exposure below the RfD (or POD/UF) while generally avoiding an extremely low limit in a single medium that represents just a nominal fraction of the total exposure. To meet this objective, all proposed numeric limits, for both quantitative and qualitative RSCs, lie between 80 percent and 20 percent of the RfD" (USEPA, 2000c). The 80 percent ceiling is protective of individuals whose total exposure is higher than average and is also protective of potential unknown sources of exposure. The EPA considers the 80 percent ceiling "If it can be demonstrated that other sources and routes of exposure are not anticipated for the pollutant in question," which, as described above, is not the case for any of the PFAS discussed in this rulemaking (USEPA, 2000c). Additionally, commenters did not provide evidence demonstrating this to be the case. Therefore, the EPA disagrees with commenters who recommend an 80 percent or higher RSC for any of the 6 PFAS.

The EPA disagrees with commenters who state that the 20 percent RSC determinations are too conservative. As stated by the 2000 *Methodology*, "When other sources or routes of exposure are anticipated but data are not adequate, there is an even greater need to make sure that public health protection is achieved" (USEPA, 2000c). Considering the evidence supporting the potential for other sources of exposure to PFOA, PFOS, PFNA, PFHxS, HFPO-DA, and PFBS besides drinking water and the lack of adequate monitoring data that would support quantification of the RSC for each of these chemicals, the agency is taking the health-protective approach in setting the RSCs at 20 percent. The selection of RSCs of 20 percent is also consistent with the definition of the MCLG. In addition, though the EPA did not ultimately rely on the noncancer/RfD approach to derive MCLGs for PFOA or PFOS, thereby not applying the RSC term to the RfD or incorporating the RSC into the MCLG calculation, the SAB PFAS Review Panel stated that, "there are non-drinking water exposures from other sources such as consumer products and house dust" and presented data from North America and Europe that support the EPA's selection of 20 percent RSCs for PFOA and PFOS (USEPA, 2022b).

The EPA disagrees with commenters who justify their stance that the cost of the EPA's rulemaking outweighs the benefits by citing to the RSC of 20 percent and stating that the PFAS NPDWR "will only help them to mitigate potentially 20%," of total exposure. As described above, this type of justification is a misinterpretation of the RSC and the 20 percent determination. Further discussion on the economic analysis supporting this rulemaking is presented in section 13 of this *Response to Comments* document.

The agency agrees with commenters who state that other actions must be taken to prevent and mitigate exposure to PFOA, PFOS, and other PFAS through sources other than drinking water. The EPA's multi-faceted approach to addressing PFAS exposure is outlined in the PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

See also Section 4.3.3 of the EPA response in this *Response to Comments* document.

4.2.5.1 Justification for the RSCs of 20% for PFOA and PFOS

New Hampshire Department of Environmental Services (NHDES) (Doc. #1690, SBC-044341)

EPA's discussion of its decision to apply a 20% Relative Source Contribution (RSC) was limited and should be expanded to clarify 1) why exposure estimates from multiple studies it cited could not be compared to the proposed RfDs and 2) why background exposures could not be estimated from NHANES studies or multiple biomonitoring studies that have been published in the peer-reviewed literature or by CDC's ATSDR (Page 18656, Column 2). Understanding exposure to background sources of PFAS, including PFOA, PFOS and their precursors, is crucial to providing an understanding of the impact of exposure reduction efforts that target drinking water. Accurate characterization of background exposures from non-drinking water sources is critical not only to the HHRA's selection of RSCs for PFOA and PFOS, but also to characterizing the uncertainties related to EPA's Benefit Analysis for potential disease burden (Section XIII-HRRCA – Page 18689, Column 3). EPA's HHRA documents for PFOA and PFOS acknowledge uncertainty about the linearity of the relationship between exposure and health effects. Better characterization and comparison of non-drinking water exposures at the proposed MCLs and health advisories would improve the understanding of the potential for overall exposure reduction relative to the RfDs and CSFs.

EPA Response: The commenter stated that the EPA's discussions supporting the RSC derivations for PFOA and PFOS were limited and requested the EPA expand this discussion to clarify why exposure estimates from the literature could not be compared to the RfDs and why background exposures could not be estimated from the available literature. The EPA provides a detailed description of RSC derivations for PFOA and PFOS, including how the data align with factors considered in the Exposure Decision Tree approach (USEPA, 2000c), in Appendix G (USEPA, 2024a; USEPA, 2024b). Please also see section 4.2.5 of the EPA response in this *Response to Comments* document. Additionally, as the EPA described in the Response to SAB Comments document (USEPA, 2023d), "biomonitoring data is not typically used to determine the RSC. While biomonitoring data provides valuable aggregate exposure information, the 2000 *Methodology for the Derivation of Ambient Water Quality Criteria* (USEPA, 2000c) does not describe an approach for deriving RSCs that use serum concentrations from the U.S. general population."

American Chemistry Council (ACC) (Doc. #1841, SBC-044836)

There have been several studies of dietary, dust, and inhalation exposure to PFOA and PFOS, none of which suggest that exposures other than drinking water are likely to add up to 80% of the allowable daily intake. [FN131: Sunderland EM et al. A review of the pathways of human exposure to poly- and perfluoroalkyl substances (PFASs) and present understanding of health effects. J Expo Sci Environ Epidemiol 29(2):131-147 (2019).] Additionally, most recently, Garnick et al. estimated an "actual RSC" for PFOA and PFOS of 0.95 based on the 95th percentile background exposures for women based on a 2011 study by Lorber and Egeghy

[FN132: Lorber M and Egeghy PP. Simple intake and pharmacokinetic modeling to characterize exposure of Americans to perfluoroctanoic acid, PFOA. Environ Sci Technology 45: 8006–8014 (2011).] and national serum concentration data from the National Health and Nutrition Examination Survey (NHANES). [FN133: Garnick L et al. An evaluation of health-based federal and state PFOA drinking water guidelines in the United States. Sci Total Environ 761:144107 (2021).] Correcting the RSC to appropriate data-driven values rather than the default would improve the defensibility of the resultant proposed MCLs. [Revision of the RSC can make a significant difference to the resulting HBWC.]

Overall Exposure to Legacy PFAS Has Declined Significantly Since 2000

As EPA is aware, four of the six substances – PFOA, PFOS, PFHxS, and PFNA - have been subject to significant new use rules (SNURs) issued by the Agency that date back as far as 2002. [FN134: SNURs addressing one of more of these four substances were issued in December 2002, October 2007, October 2013, and July 2020.] Most of these rules have followed voluntary commitments from US-based manufacturers to phase out the production and use of the materials. As a consequence, exposure to these four substances from the manufacture and use of products containing them has declined substantially. This is reflected in biomonitoring data collected by the Centers for Disease Control and Prevention (CDC) as part of its National Health and Nutrition Examination Survey (NHANES). [FN135: https://www.cdc.gov/exposurereport/index.html.]

[Figure 1: see docket ID EPA-HQ-OQ-2022-0114-1508]

Figure 1. Mean Serum levels of PFOA and PFOS (micrograms per Liter), 1999-2016 [FN136: Ibid.]

The CDC results suggest a nearly 75 percent drop in exposure to PFOA and about a 90 percent drop in PFOS exposure between 1999 and 2018. (See Figure 1.) [FN137: The graph does not include data from the 2017-18 NHANES survey which reported levels of 1.42 µg/L for PFOA and 4.25 µg/L for PFOS.] Although not as commonly used in manufacturing historically, exposures to PFHxS and PFNA have also declined over this time period (50 percent for PFHxS, 25 percent for PFNA) according to the NHANES data.

Dietary sources have been suggested as a major contributor to exposures to various PFAS. Data from the Food and Drug Administration's (FDA) Total Diet Study suggest, however, that exposure to PFOA, PFOS, PFHxS, and PFNA have been all but eliminated. [FN138: https://www.fda.gov/media/150338/download.] Of the 94 food products FDA sampled as part of a 2020 survey, PFOA and PFHxS were not detected in any samples and PFNA and PFOS were detected in only one. This further supports the notion that the RSC default is inappropriate as non-drinking water sources of these four PFAS are continuing to decline.

While exposures to these four PFAS from dietary sources, consumer products, ambient air, and household dust have declined over the past twenty years as a result of the phaseout of their manufacture, exposure from drinking water has gone largely unaddressed. As EPA notes in its

Economic Analysis, standard treatment methods employed by public water systems do not remove PFAS from source water. As a result, drinking water has likely become an increasingly greater contributor to overall exposures to these substances. The upcoming Unregulated Contaminant Monitoring Rule 5 (UCMR5) data, which should become availability within this next year, will help define the frequency of occurrence and concentrations of these PFAS in our Nation's public drinking water systems. The EPA should wait until this information is available to make judgements about PFAS drinking water exposure.

EPA Response: Please see section 4.2.5 of the EPA response in this *Response to Comments* document. The commenter cited two studies that discussed the relative contribution of various exposure media/sources to human PFOA or PFOS exposures. The studies cited did not derive RSCs using methods described in the *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (USEPA, 2000c), which explicitly states data requirements for quantitative data-driven RSC derivation. The EPA describes the data and rationale used to derive RSCs for PFOA and PFOS in Appendix G (USEPA, 2024a; USEPA, 2024b). The commenter additionally mischaracterized the conclusions of Sunderland et al. (2019) (see Table 1 of Sunderland et al., 2019).

The EPA also notes that the derived RSCs have no impact on the MCLGs for PFOA or PFOS finalized in this rulemaking because the MCLGs are zero based on the determination that PFOA and PFOS are *Likely to be Carcinogenic to Humans,* not on an RfD-based MCLG derivation approach (see USEPA, 2024e). However, even if the EPA had used an RfD-based approach and selected the least stringent RSC (i.e., the ceiling of 80 percent (USEPA, 2000c)), the MCLGs for PFOA and PFOS would still be below the MCL of 4 ppt. See the calculations presented in the EPA response to comment Doc. #1713, SBC-053421 in section 4.2.1.4 in this *Response to Comments* document. If the EPA had substituted a "0.8" for the "0.2" in the equations, the noncancer-based MCLGs for PFOA and PFOS would be 0.7 ng/L (ppt) and 2 ng/L (ppt), respectively.

See section 6.8 of the EPA response in this *Response to Comments* document for discussion related to data collected under UCMR 5.

4.2.5.2 PFAS Exposure Sources

Massachusetts Coalition for Water Resources Stewardship (MCWRS) (Doc. #1691, SBC-044324)

The public health benefits of the proposed MCL cannot be determined if there is no full understanding of PFAS exposure levels from various sources. It is well documented that PFAS is present, often in high concentrations, in household products, personal care products, food, dust, clothing, fabric, food wrappers and a multitude of materials to which people are routinely exposed every day. EPA assumed 20% of exposure is from drinking water but this is the default value, not an estimate, and not based on any data. It is not possible to claim massive public health benefits from the proposed MCLs when there is no understanding of exposure levels from

other common sources. Imagine if childhood lead poisoning had been handled in a similar fashion. If the approach to reducing lead exposure had been to just regulate drinking water then lead based paint, by far the greatest source of lead intake for children, would have been ignored and little progress would have been made addressing this very real health issue. For most Americans, PFAS intake from drinking water could be 1% or less of the total PFAS exposure. Spending $40 billion or more to reduce PFAS exposure by 1% does not appear to be a sound public health strategy or wise use of public monies.

EPA Response: Please see section 4.2.5 of the EPA response in this *Response to Comments* document, as well as documentation describing the rationale and process for the RSCs derived for PFOA (USEPA, 2024a), PFOS (USEPA, 2024b), and PFNA, PFHxS, PFBS, and HFPO-DA (USEPA, 2024h).

American Chemistry Council (ACC) (Doc. #1711, SBC-044461)

[The Agency's proposal suffers from the following significant shortcomings –]

• The Agency's assumptions about the contribution of drinking water to overall exposure to the identified substances ignores the available biomonitoring and food survey data,

EPA Response: Please see section 4.2.5 of the EPA response in this *Response to Comments* document. The commenter incorrectly states that the EPA ignores the available biomonitoring and food survey data. Biomonitoring data were discussed in Section 1.6.1 of the PFOA and PFOS draft toxicity assessments (USEPA, 2023f; USEPA, 2023a) and Section 1.4.1 of the final PFOA and PFOS toxicity assessments (USEPA, 2024d; USEPA, 2024c). Occurrence in food is discussed in Appendix G (USEPA, 2024a; USEPA, 2024b). According to established EPA methodology (USEPA, 2000c) and as described in the EPA response to SAB comments document (USEPA, 2023d), biomonitoring data are not generally used to determine the relative source contribution.

HRSD (Doc. #1719, SBC-043549)

Finally, and linking back to the earlier discussion on the criticality of source control, EPA needs to reconsider its choice of Relative Source Contribution (RSC) factor for each of the PFAS compounds. The selected RSC of 0.2 essentially puts the burden of controlling 80% of our PFAS exposure on the water sector, which equates to an unfair cost burden on the communities being served. EPA must work with other federal agencies to reduce the public exposures of PFAS and push impactful and cost- effective reductions in exposure. Forcing more stringent controls on the water sector to essentially compensate for the failure to control PFAS from other sources is simply unreasonable and infeasible. True public health protection requires a robust program of source control to mitigate public health exposures.

EPA Response: The commenter erroneously stated that the EPA's selection of a 20 percent RSC for each of the 6 PFAS considered under this rule effectively means that 80 percent

of the burden of PFAS reduction will be placed on the water sector. This statement reflects a fundamental misunderstanding of both what the RSC is and what the basis of some of the MCLGs and MCLs are for these PFAS. First, please see section 4.2.5 of the EPA response in this *Response to Comments* document. Additionally, the derived RSCs have no impact on the MCLGs for PFOA or PFOS because the MCLGs are based on the determination that PFOA and PFOS are *Likely to be Carcinogenic to Humans,* not on an RfD-based MCLG derivation approach. Please also see the EPA response to comment Doc. #1841, SBC-044836 in section 4.2.5.1 in this *Response to Comments* document.

4.2.6 Recommended Literature

Summary of Major Public Comments and EPA Responses

A few commenters expressed support of the EPA's effort to conduct a final literature search update prior to finalization of the toxicity assessments for PFOA and PFOS. Many commenters provided citations for the EPA to consider during finalization.

The EPA has reviewed and documented the literature identified from the updated search conducted in February 2023, in accordance with the systematic review protocols developed for the PFOA and PFOS toxicity assessments (see Appendix A.1 of USEPA (2024a) and USEPA (2024b)). Results of this effort are discussed in the final toxicity assessments (see Appendices A.3 and A.4 of USEPA (2024a) and USEPA (2024b)). Documentation for the EPA's review of references recommended by commenters is provided in a tabular format in the docket (EPA-HQ-OW-2022-0114) and is summarized in Section 3.1 of the final toxicity assessments (USEPA, 2024d; USEPA, 2024b).

Many commenters noted differences between the conclusions of the EPA's toxicity assessments for PFOA and PFOS and the assessments and conclusions published by other agencies or the EPA's previously published assessments (e.g., the 2016 HESDs). Commenters recommended the EPA consider publications by the ATSDR, World Health Organization (WHO), National Toxicology Program (NTP), EFSA, Food Safety Australia and New Zealand (FSANZ), the United Kingdom's Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment (COT), HC, Texas Commission on Environmental Quality (TCEQ), NJDEP, and Michigan Science Advisory Workgroup, among others when finalizing its toxicity assessments for PFOA and PFOS.

There are several reasons why the EPA's conclusions may differ from those of other health agencies or from the agency's previous conclusions. For example, commenters questioned why the EPA's conclusions regarding the associations between adverse immunological endpoints and PFOA and PFOS exposure differ from the report on immunotoxicity of PFOA and PFOS developed by NTP (2016). First, the NTP (2016) report is approximately 8 years old and does not account for the more recent information the EPA considered in the final PFOA and PFOS toxicity assessments (USEPA, 2024d; USEPA, 2024c). As shown repeatedly through the EPA's literature searches conducted for these assessments, thousands of studies on PFOA and PFOS have been

published since that time; many of the critical studies the EPA considered postdate the 2016 NTP report, including the Timmerman et al. (2021), Zhang et al. (2023), and Budtz-Jørgensen and Grandjean (2018) critical studies. The EPA's conclusions regarding the immune health outcome reflects the best available peer-reviewed science. Another explanation for differing conclusions between health agencies are the differing methods and guidance used to develop the assessments. The EPA uses established systematic review practices (USEPA, 2022a) to identify, evaluate, synthesize, integrate, and quantify evidence in a chemical database. Other health agencies, including the WHO, do not follow these same practices and, as a result, may arrive at different conclusions. Additionally, the EPA followed agency guidance, such as the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) to determine the cancer classifications for PFOA and PFOS. The classification systems used by other agencies (e.g., IARC, UK COT, CalEPA) differ from those used by the EPA; the application of different systems may result in different conclusions by other agencies. However, CalEPA's final public health goals are also generally supportive of the EPA's cancer classifications for PFOA and PFOS (CalEPA, 2024). As a final example, some agencies, such as the WHO have published guidance values that are not solely health based (i.e., they consider feasibility, analytical methods, etc.) and therefore, cannot be directly compared to the EPA's MCLGs, which are based solely on health effects information. The MCLs published in this rulemaking (described in section V of the rule preamble and section 5 of this *Response to Comments* document) may be more comparable to guideline values published by external agencies than the MCLGs described in this section.

Some comments pointed out differences between the EPA's and other agencies' conclusions, with references to specific cancer or noncancer effects. Please refer to section 4.1.4 of this *Response to Comments* document and Section 3.5 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c) regarding the EPA's conclusions about cancer effects. Please refer to section 4.2.1 of this *Response to Comments* document and Section 3.4 of the final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c) regarding the EPA's conclusions about noncancer effects, including effects on the immune system, development, cardiovascular system, and liver.

Individual Public Comments and EPA Responses

Savannah River Nuclear Solutions LLC (Doc. #1647, SBC-043343)

The support document, Public Comment Draft Toxicity Assessment and Proposed Maximum Contaminant Level Goal for PFOA in Drinking Water publishes a PFOA overall reference dose (RfD) = 3E-08 mg/kg/day (page 4-53) and selects a CSF = 0.0293 (ng/kg/day)-1 (page 4-59). The EPA May 2023 regional screening levels (RSL) website publishes a RfD = 3E-06 mg/kg-day and a CSF (SFo) = 7E-02 (mg/kg-day)-1.

Further, support document Public Comment Draft Toxicity Assessment and Proposed Maximum Contaminant Level Goal for PFOS in Drinking Water publishes a PFOS overall RfD = 1E-07 mg/kg/day (page 4-49) and selects a cancer slope factor (CSF) = 39.5 (mg/kg/day)-1 (page 4-51). The EPA May 2023 RSL website publishes a RfD = 2E-06 mg/kg-day and a CSF (SFo) = none.

SRSNS requests that EPA explain why there is such a large difference between the toxicity values (RfD and CSF) published in the Draft Toxicity Assessments compared to those published in the most current EPA RSL website. In contrast, the RfDs for the PFAS mixtures (GenX, PFBS, PFNA, PFHxS) align with the values in the RSL website, minor exception is that PFHxS applies an additional sub-chronic to chronic uncertainty factor of 10 that is not considered in the RSL website (per the Public Comment Draft MCLG Summary for a Mixture of Four Per- and Polyfluoroalkyl Substances (PFAS): GenX, PFBS, PFNA and PFHxS).

EPA Response: The commenter requested clarification on why there are differences between the toxicity values presented in the EPA's draft toxicity assessments for PFOA and PFOS and those previously presented as the EPA Regional Screening Levels (RSLs). RSLs are not established under the authority of the Safe Drinking Water Act and instead are established as one of many tools to support Comprehensive Environmental Response Compensation and Liability Act (CERCLA) superfund implementation. The agency's Superfund program, in accordance with the 2003 memo "Human Health Toxicity Values in Superfund Risk Assessments" (USEPA, 2003b), generally uses final, peer reviewed, publicly available toxicity values (such as the ATSDR values) to calculate RSLs and RMLs. Draft toxicity assessments, such as those developed in support of the proposed PFAS NPDWR (USEPA, 2023f; USEPA, 2023a), are not used in calculating the RSL and RMLs. The finalized toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c) will be considered as part of the semi-annual update of RSLs and RMLs. The RSLs referenced by the commenter were based on toxicity assessments that predate finalization of the toxicity assessments for PFOA and PFOS. Further discussion on the RSL and RML update processes are outside the scope of this rulemaking.

Missouri Department of Natural Resources (Doc. #1563, SBC-042515)

EPA requests comment on whether there are other peer-reviewed health or toxicity assessments for other PFAS the Agency should consider as a part of this action.

While the Department has not evaluated the report, we were made aware of the following study which may or may not be relevant to this action: Henry, B. J., et al. "A critical review of the application of polymer of low concern and regulatory criteria to fluoropolymers", Integrated Environmental Assessment and Management. Volume 14, number 3, pages 316-334. May 2018.

EPA Response: Please see section 4.2.6 of the EPA response in this *Response to Comments* document.

New Hampshire Department of Environmental Services (NHDES) (Doc. #1690, SBC-044336)

Third, the EPA's human health risk assessment of PFOA and PFOS is a significant departure from its 2016 interpretation of similar studies. NHDES appreciates the growing body of scientific literature about the potential health impacts following PFAS exposure. However, the current technical support documents lack clarity about how the EPA's current approach is consistent with the assessment of previous chemicals with similar health endpoints. Similarly, it

is unclear how EPA has determined that this approach is reasonable for any and all chemicals with similar properties or how it will apply this level of conservatism to future chemical risk assessments. Furthermore, the assessments do not reflect existing evidence for the multiple sources of PFAS exposure from the environment and consumer products in addition to drinking water.

In conclusion, NHDES appreciates the opportunity to provide comments on the US EPA's proposed MCLs for PFAS. As a state that has been significantly impacted by PFAS contamination and has developed considerable expertise on the topic, we understand the importance of both science-based rulemaking and a thorough review of public comment provided by a broad array of stakeholders. We trust that our constructive comments will be incorporated as the EPA moves forward to advance this important rulemaking.

EPA Response: Please see section 4.2.6 of the EPA response in this *Response to Comments* document. Further, in 2016, the EPA had not yet adopted the currently established systematic review methodologies (i.e., USEPA, 2022a) used to develop the assessments supporting this rulemaking. In addition, hundreds of peer-reviewed epidemiological and animal toxicological studies on PFOA and PFOS have been published since the 2016 assessments as detailed in Section 3.1 of the toxicity assessments (USEPA, 2024d; USEPA, 2024c). The commenter does not provide specific instances where the EPA is inconsistent in its assessment of previous chemicals with similar health endpoints or which aspects of the current assessment are conservative.

The commenter additionally stated that the PFOA and PFOS toxicity assessments did not reflect existing evidence for multiple sources of PFAS exposure. This is incorrect. The EPA provides a detailed description of studies reporting the occurrence of PFOA or PFOS in various environmental media in Appendix G (USEPA, 2024d; USEPA, 2024c). In this appendix, the EPA also states that there are potentially significant sources of PFOA or PFOS exposure other than drinking water, including dietary sources, dust, consumer products, and air. This information is reflected in the EPA's derivation of relative source contributions (RSCs) of 20 percent for both PFOA and PFOS in drinking water. Regarding this topic, please also see section 4.2.5 of the EPA response in this *Response to Comments* document.

Michigan Farm Bureau (Doc. #1562, SBC-052842)

The different recommendations and regulatory limits on PFAS in drinking water and other media from different organizations and entities reflect the profound uncertainty and developing research on the potential for health impacts due to PFAS exposure. The Agency for Toxic Substances and Disease Registry (ASTDR) developed an overview of science and clinical guidance for PFAS, [FN2: ASTDR. 2019. PFAS: An Overview of the Science and Guidance for Clinicians on Per- and Polyfluoroalkyl Substances. Retrieved from: https://www.atsdr.cdc.gov/pfas/docs/clinical-guidance-12-202019.pdf.] noting that human studies on PFAS-associated health impacts have a lack of exposure monitoring data, limited analysis of other routes of exposure, and for many of

the predicted health impacts, no causal relationship has been established by these studies. ASTDR noted that the ability to quantify and associate incidence of health impacts for other PFAS was even less documented than PFOS and PFOA.

In a separate report, [FN3: ASTDR. 2021. Toxicological Profile for Perfluoroalkyls. U.S. Department of Health and Human Services. Retrieved from: https://www.atsdr.cdc.gov/ToxProfiles/tp200.pdf.] the ASTDR noted that differences in half-life of PFAS, mechanism of toxicity and endpoints, and differences in exposures created a high degree of difficulty in comparing animal studies to human health risks due to PFAS exposure. In particular, rats and mice used in experimental studies have more sensitive receptors that mediate a wide range of biological responses to chemical exposure that humans and other primates are far less sensitive to. Animal studies also predominantly focus on oral exposure without corroborating evidence collected for dermal or inhalation exposure, limiting the pathways for understanding of PFAS impacts from real-world contact. This is especially important for evaluating health impacts to other PFAS chemicals besides PFOA and PFOS, which have several human epidemiological studies to support and validate animal studies and models, making the establishment of hazard indices or limits to other PFAS problematic. Additionally, the study noted that "adverse health effects in studies in animals have been associated with exposure concentrations or doses that resulted in blood levels of perfluoroalkyls that were significantly higher than those reported in perfluoroalkyl workers or in the general population. [FN4: Id., p.7.] While not intended to cast doubt on whether PFAS exposure can have human health impacts, this study highlights the challenges in establishing meaningful MCLs and Maximum Contaminant Level Goals (MCLGs).

The U.S. Department of Health and Human Services' National Toxicology Program (NTP) performed a literature review [FN5: National Toxicology Program. 2016. NTP Monograph: Immunotoxicity Associated with Exposure to Perfluorooctanoic Acid of Perfluorooctane Sulfonate. U.S. Department of Health and Human Services. Retrieved from: https://ntp.niehs.nih.gov/ntp/ohat/pfoa_pfos/pfoa_pfosmonograph_508.pdf.] of health impact studies related to PFOS and PFOA and how the studies were both mechanistically analyzed and weighted for both potential bias of results and level of confidence in the evidence presented. The NTP concluded that while there was a high level of confidence in the evidence associating immune hazards in animals from exposure to PFOA and PFOS, there was only moderate confidence in associating immune hazards in humans from such exposure. While the NTP report concluded there is a high likelihood of health impact to humans from PFOS and PFOA exposure, their report highlights the difficulty of assigning risk to specific exposures because of a lack of epidemiological evidence on humans.

Similarly, research conducted on the European Food Safety Authority's assessment of PFAS risk [FN6: Antoniou E, Colnot T, Zeegers M, Dekant W. 2022. Immunomodulation and exposure to per- and polyfluoroalkyl substances: an overview of the current evidence from animal and human studies. Archives of Toxicology;96(8):2261-2285. doi: 10.1007/s00204-022-03303-4. Epub 2022 Jun 13. PMID: 35695909.] showed a weak relationship between PFAS blood serum levels and

immune response (which was the basis of the overall risk assessment), until blood serum levels are at several orders of magnitude higher than the geometric mean of European blood serum levels, which are 2.13 parts per billion (ppb) for PFOS and 0.97 ppb of PFOA. These values are compared to the geometric mean of general US population blood serum concentrations, which are 4.28 ppb for PFOS and 1.42 ppb for PFOA. [FN7: Centers for Disease Control and Prevention. 2022. Biomonitoring Data Tables for Environmental Chemicals. Retrieved from: https://www.cdc.gov/exposurereport/data_tables.html.]

The World Health Organization (WHO) reported [FN8: World Health Organization. 2022. PFOS and PFOA in Drinking Water: Background Document for Development of WHO Guidelines for Drinking-water Quality, Version for Public Review issued 29 September, 2022. WHO/SDE/WSH/XXXXXX. Retrieved from: https://www.cmbg3.com/library/WHO-Draft-Drinking-Water-Document.pdf] a wide variation in study results for varying health impacts from PFOS and PFOA exposure, finding that there was insufficient evidence for causal relationships between PFOA and PFOS and several health impacts studies have suggested are associated with PFAS. The health conditions tested with uncertain causal relationships to PFAS include: maternal hypertension/pre-eclampsia, pre-term birth and pregnancy loss (though PFOA had a stronger statistical association with this impact, making a causal relationship more likely), male reproductive fertility, neurodevelopmental abnormalities, overweight conditions in childhood, heart defects, neurotoxicity in adults, endocrine disorders, cardiovascular disease, diabetes, adult obesity, liver disease, chronic kidney disease, and PFOS impacts on cancer development. This report does not dispute the association between PFAS and health impacts, but further highlights the uncertainty surrounding health impacts from exposure. It additionally summarizes the range of PFAS health-based advisories and drinking water regulations, which go from 3 to 400 ppt for PFOS and 4 to 100 ppt for PFOA, noting that these standards used many different analytical methods to reach their concentration limits, and setting their own provisional guideline value of 500 ppt for all combined PFAS, and 100 ppt each for PFOA and PFOS.

The uncertainty noted in these reports is important because it highlights the need to develop robust and consistent tools to analyze data used to set health risk values and weight them appropriately against the feasibility of implementation and compliance with regulatory drinking water treatment standards.

EPA Response: For explanations of why the EPA's assessment conclusions may differ from other agency conclusions, please see section 4.2.6 of the EPA response in this *Response to Comments* document. For discussion on the use of epidemiological studies to support qualitative and quantitative risk assessments, please see section 4.2.2 of the EPA response in this *Response to Comments* document. For discussion on the other four PFAS considered in this rulemaking, please see section 4.3 of the EPA response in this *Response to Comments* document.

Mass Comment Campaign sponsored by Alliance for Risk Assessment (Doc. #1606, SBC-042828)

We read with surprise the recent action by EPA regarding the development of its PFOA MCL based in part on the development of its prior PFOA MCLG, and its associated reference or safe dose. EPA must know that its safe dose is over 100,000-fold lower than other international authorities, specifically FSANZ (2017), and significantly lower, although not quite as dramatically, with Health Canada (2018), WHO (2022), and more recently Burgoon et al. (2023). Moreover, all four of these expert groups concluded, in contrast to EPA, that the observational epidemiologic data do not constitute a reliable basis for estimating a reference dose for PFOA in the absence of mechanistic data that are relevant for humans at serum concentrations seen in the general population.

We encourage our EPA colleagues to seriously consider these other expert, international positions, and to engage colleagues associated with one or more of these groups in a resolution. Towards this resolution, a workshop is being planned for October of this year under the auspices of the Alliance for Risk Assessment (ARA), details of which will be forthcoming at https://www.tera.org/Alliance%20for%20Risk/ARA_Dose-Response.htm.

EPA Response: For explanations of why the EPA's assessment conclusions may differ from other agency conclusions, please see section 4.2.6 of the EPA response in this *Response to Comments* document. Regarding the EPA's quantitative and qualitative use of epidemiological data in these assessments, please see section 4.2.2 of the EPA response in this *Response to Comments* document.

Greater North Dakota Chamber et al. (Doc. #1593, SBC-042803)

There is limited understanding of risk at these levels. There is significant uncertainty regarding the health risks at the proposed MCL levels for all six PFAS. WHO's recent study on potential guidelines for water quality, for example, proposed 100 ppt based on the most relevant public health data and seems to be consistent with known risk.

EPA Response: For explanations of why the EPA's assessment conclusions for PFOA and PFOS may differ from other agency conclusions, please see section 4.2.6 of the EPA response in this *Response to Comments* document. Please see section 4.3 of the EPA response in this *Response to Comments* document for discussion on the other four PFAS considered under this rulemaking.

Aurora Water, City of Aurora, CO (Doc. #1669, SBC-043731)

The American Chemical Society (ACC) has voiced their concerns about the science behind EPA's proposed MCLs. Aurora Water agrees with their concerns about the excessively high health threshold for PFOA and PFOS. As noted by ACC, the World Health Organization (WHO) has stated they cannot set an official Health-Based Guidance Value with confidence. When determining the health impacts from PFAS the EPA should consider other organizations' positions about those impacts.

EPA Response: For explanations of why the EPA's assessment conclusions for PFOA and PFOS may differ from other agency conclusions, please see section 4.2.6 of the EPA response in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-053455)

EPA did not act on SAB recommendations to consider the conclusions of other agencies regarding immune effects as a critical endpoint, and in particular, the Grandjean et al. (2012) study.

EPA's use of human epidemiologic data as the sole basis for its calculations regarding vaccine response is a departure from the conclusions of other U.S. regulatory agencies. The SAB recommended that EPA review and potentially include conclusions from other agencies about immune outcomes. The EPA's response was that it "considered the conclusions from other health agencies about both the immune endpoints in general and the Grandjean et al. (2012) study in particular." However, EPA does not appear to have considered either the Agency for Toxic Substances and Disease Registry (ATSDR) or National Toxicology Program's (NTP) conclusions regarding immune endpoints. Both U.S. agencies raised questions regarding the reliability of human studies for the purposes of dose-response and risk assessment.

In addition to reviewing other agencies' conclusions regarding immune outcomes, the SAB also suggested that EPA should review the comments on Grandjean et al. (2012) and the studies of the Faroe Islands cohorts, in particular. It does not appear that EPA adequately addressed the SAB's suggestion.

In the NTP's review of the immunotoxicty of PFOA and PFOS, the agency stated that Grandjean et al. (2012) accounted for PCB exposure in analyses, but not PFAS. Therefore, "unless a study controlled for other PFAAs, studies were rated probably high risk of bias in accounting for potential confounders and modifiers because of the limited ability to differentiate effects of PFOA or PFOS from other PFAAs" (NTP 2016, p. 26). The NTP also noted that the findings may be due to chance, given the number of comparisons made in the analyses. Due to the non-significant results in the Mogensen et al. (2015) re-analyses of the Faroe Islands cohort, controlling for other PFAS, "Confidence in the body of evidence was not increased for dose-response for several reasons including the difficulty in attributing effects to individual compounds" (NTP 2016, p. 31).

ATSDR also pointed out that "Grandjean and associates also found an inverse association between serum polychlorinated biphenyls (PCBs) and serum antibody concentrations against tetanus and diphtheria in children living in the Faroe Islands (Heilmann et al. 2010)." ATSDR found that there was moderate confidence that exposure to PFOA is associated with suppression of the antibody response based on available human studies (ATSDR 2021, p. 327), and ultimately concluded that "the available epidemiological studies suggest associations between perfluoroalkyl exposure and several health outcomes; however, cause-and-effect relationships have not been established for these outcomes", including decreased antibody response to vaccines (ATSDR 2021, p. 6).

EPA failed to provide further consideration of the limitations of the Faroe Island studies identified by other agencies in its assessment of immune outcomes. These considerations would have informed EPA's decision regarding candidate studies as well as vaccine response as a critical endpoint.

EPA Response: The commenter states the EPA did not review and consider conclusions from other health agencies about immune endpoints. The commenter claimed the EPA did not follow recommendations of the SAB. The commenter provides limitations described by each health agency's documents characterizing immunotoxic effects of PFOA and PFOS, and the commenter suggests these limitations were not considered in the EPA's conclusion on immune effects. The EPA disagrees with these comments and first directs the commenter to sections 4.2.6 and 4.1.3 of the EPA response in this *Response to Comments* document.

Additionally, the commenter incorrectly characterizes the conclusions from both NTP's review (NTP, 2016) and ATSDR's *Toxicological Profile for Perfluoroalkyls* (ATSDR, 2021). Despite the limitations outlined by the commenter, NTP concluded that PFOA and PFOS are "presumed to be immune hazard to humans and to alter immune functions in humans," which was based on "a moderate level of evidence from studies in humans" (NTP, 2016, p. 86).

The ATSDR's *Toxicological Profile for Perfluoroalkyls* also identifies literature about the health effects of PFOA and PFOS and notes "epidemiological studies identify the immune system as a target of perfluoroalkyl toxicity," and that "the strongest evidence of the immunotoxicity of perfluoroalkyls in humans comes from epidemiological studies finding associations evaluating the antibody response to vaccines" (ATSDR, 2021). The ATSDR *Toxicological Profile* does not provide a classification or determination for PFOA and PFOS but notes the strength of the evidence base.

The commenter also mischaracterizes the SAB's conclusions about the immune endpoint and the Grandjean et al. (2012) study. In the final report, the SAB stated: "Overall, the Panel agreed with the selection of the critical study, Grandjean et al. (2012), and the critical effect, suppression of a vaccine response in children exposed during development, as appropriate for the derivation of chronic RfDs for PFOA and PFOS." The EPA considered all recommendations of the SAB when revising the assessments of PFOA and PFOS, including their overall conclusions on the EPA's assessments, as well as recommendations to consider the conclusions of other health agencies.

Additionally, the critical study selected for the immune health outcome-specific RfD was Budtz-Jorgensen & Grandjean (2018), which reflects updated analyses of the cohort studied by Grandjean et al. (2012).

PFAS Regulatory Coalition (Doc. #1761, SBC-053404)

Further, EPA is inconsistent in its decisions as to the toxicological endpoints that it wants to rely on. The HALs that EPA issued in 2022 were based on immune response, whereas the conclusions in the EPA Proposal appear to be based on cancer studies in mice and rats. Which endpoint does EPA think is appropriate to use? EPA does not provide any explanation of why it has chosen different endpoints for the HAL than in the current Proposal.

EPA Response: The EPA disagrees with the commenter's statement that the agency is "inconsistent in its decisions as to the toxicological endpoints that it wants to rely on." The commenter appears to misunderstand the processes used to develop the interim HAs for PFOA and PFOS and the final toxicity assessments and MCLGs for PFOA and PFOS.

In 2021, the EPA published and transmitted two draft documents, the *Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) (CASRN 335-67-1) in Drinking Water* (USEPA, 2021b) and the *Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) (CASRN 1763-23-1) in Drinking Water* (USEPA, 2021c), to the SAB PFAS Review Panel for peer review. Those documents were the basis for the qualitative and quantitative conclusions of the interim HAs for PFOA and PFOS, published in 2022. The 2022 interim HAs were based on noncancer endpoints (i.e., reduced antibody response to vaccination in children) and are non-regulatory HAs issued pursuant to a separate authority under SDWA that reflected the best available information at that time.

With the conclusion of the peer review process (see USEPA (2022b)), the EPA revised and improved the 2021 draft documents (USEPA, 2021b; USEPA, 2021c) and subsequently published updated draft toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a), as well as proposed MCLGs for PFOA and PFOS at the time of the PFAS NPDWR proposal (USEPA, 2023e). The proposed rule and draft toxicity assessments for PFOA and PFOS (USEPA, 2023f; USEPA, 2023a) were published for public comment at that time.

The proposed and final MCLGs are set to zero based on the EPA's cancer determinations that PFOA and PFOS are *Likely to Be Carcinogenic to Humans* in accordance with the *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005) (see Section 4.1.5 of the EPA response in this *Response to Comments* document). The determinations of *Likely to Be Carcinogenic to Humans* are based on reviewing the weight of the evidence of the best available data from human epidemiology, animal toxicology, and mechanistic studies (see Section 4.1.4 of the EPA response in this *Response to Comments* document); in contrast to the commenter's statement, the MCLGs are not solely based on cancer studies in rodents.

At the time of rule proposal, the EPA communicated the differences in underlying toxicity values between the 2021 and 2023 draft toxicity values in this transparent note on the EPA's PFAS HA webpage (https://www.epa.gov/sdwa/drinking-water-health-advisories-pfoa-and-pfos). Specifically, the EPA stated, "In the proposed rule, EPA presents updated noncancer toxicity values based on evaluating additional scientific information. These updated values are different from those used to calculate the 2022 interim HAs, which EPA based on the best available science at that time." The 2023 toxicity assessments released as part of the rule proposal considered SAB recommendations and new scientific information. The EPA has considered information from an updated literature review and the information and studies reviewed were confirmatory of the EPA findings and conclusions in the PFOA and PFOS toxicity assessment drafts released for public comment at the time of rule proposal (USEPA, 2023f; USEPA, 2023a). The EPA final rule and final toxicity assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c) reflect the best available science and consideration of the public comments. As discussed in this *Response to Comments* document and throughout the administrative record for this action, the PFOA and PFOS MCLGs in the final rule are zero.

Anonymous (Doc. #1964, SBC-046609)

I would like to bring to the agency's attention new research that is highly relevant for the decision-making process regarding the proposed regulation Per- and Polyfluoroalkyl Substances National Primary Drinking Water Regulation, Docket (EPA-HQ-OW-2022-0114).

The proposed regulation text cites that depending on the individual PFAS, health effects can include negative impacts on fetal growth after exposure during pregnancy, on other aspects of development, reproduction, liver, thyroid, immune function, and/or the nervous system; and increased risk of cardiovascular and/or certain types of cancers, and other health impacts when providing context for the following regulatory actions: proposing a National Primary Drinking Water Regulation (NPDWR) and health-based Maximum Contaminant Level Goals (MCLG) for these four PFAS and their mixtures as well as for PFOA and PFOS.

The related research summarized below supports the data presented by the agency...

This study childhood PFAS exposures may be associated with elevated serum lipid concentrations. This is a public health concern, as a detrimental lipid profile in childhood is a risk factor for later development of hyperlipidemia and cardiovascular disease.

There is strong evidence supporting a link between PFAS exposure and increased glucose levels and insulin resistance, with a strongest association in groups with multiple risk factors for diabetes. Although there appears to be variable associations, the conflicting data is often related to the specific PFAS examined and the gender of the subject affected.

The most consistently observed and strongest evidence for harmful impacts on human health is for immune suppression (such as decreased vaccination response), changes in liver function (such as higher cholesterol, elevated liver enzymes), and lower birth weight. In addition, PFOA

has also been associated with kidney cancer. Increased tumors were also observed in certain organs in animals exposed to very high doses of PFOA.

A comprehensive study estimates the societal costs for not regulating PFAS. The costs relate to health impacts of workers and the general population following PFAS exposure in addition to costs for cleaning up contaminated soil and water is estimated to be billions of Euros.

While we believe the immediate health risks for most people exposed to PFAS are low, the latest information indicates that fetuses and infants are more vulnerable. Long term exposure to PFOA, PFOS, and PFHxS leads to a buildup of these chemicals in women of child-bearing age that increases exposure to the fetus and breastfed babies. Breastfeeding provides many health benefits for mothers and babies.

The sources for the research cited above can be found at the end of this comment.

Please take this research into consideration when making any adjustments for the final regulation.

Sincerely,

Julien Tremblay and additional MD/MPH Degree Candidates

Emma Nal (Doc. #2427, SBC-046449)

This is a great start but the regulation needs to go further to protect human health. Please read this research:

https://news.harvard.edu/gazette/story/2023/05/epas-new-rules-on-forever-chemicals-dont-go-far-enough-study-suggests/?utm_source=SilverpopMailing&utm_medium=email&utm_campaign=Daily%20Gazette%2020230517%20(1)

EPA Response: Please see section 4.2.6 of the EPA response in this *Response to Comments* document.

4.2.7 Recommendations for Additional Research

Millie Garcia-Serrano (Doc. #1803, SBC-044290)

Overall, as movement is made toward better regulation and oversight of these contaminants, ASTSWMO's membership recognizes a corresponding need for research, communication, and improved understanding within the following areas:

• development of human health and ecological toxicity values for PFAS;

EPA Response: The EPA agrees that development of human health and ecological toxicity values for PFAS are important. For all the ways the EPA is working to address PFAS pollution and exposure, please see the PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Anonymous (Doc. #1958, SBC-046295)

The EPA should do more research on how PFAS affects the human body in the long run. These chemicals have been proven to cause multiple health defects, such as cancer and liver problems. In addition, PFAS is a difficult compound for the human body to break down, so the more people consume it in drinking water, the more likely their health will deteriorate. Before putting this rule into law, the EPA should make efforts to do more experiments and conduct more research on these harmful chemicals so that a large portion of the population does not have their heath at risk when drinking water.

EPA Response: The EPA disagrees that more research needs to be done to finalize this PFAS NPDWR. The EPA is publishing Final Human Health Toxicity Assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c); these assessments consider hundreds of studies reporting adverse health effects that are associated with long-term exposure to PFOA and PFOS. Similarly, the agency has substantial information supporting NPDWR finalization for the four additional PFAS considered in this rulemaking (i.e., PFNA, PFHxS, HFPO-DA, and PFBS). See sections 4.3 and 5 of the EPA response in this *Response to Comments* document for information on the Hazard Index MCLG and MCLs, respectively.

Monte Vista Water District (MVWD) (Doc. #1718, SBC-043532 & SBC-043538)

In conclusion, MVWD's top priority is delivering safe drinking water, and we support EPA's efforts to ensure public health by monitoring and reducing exposure to PFAS contamination in drinking water. MVWD supports scientific research on potential health effects and exposure pathways to better understand the toxicity, bioaccumulation, and long-term health impacts of PFAS. MVWD recommends additional research, analysis, and monitoring efforts to better understand the extent of PFAS in drinking water to ensure science-based decision-making in support a more comprehensive PFAS National Primary Drinking Water Regulation.

EPA Response: Several of the comments provided by this commenter support the final rule. However, the EPA disagrees that more research needs to be done to finalize this PFAS NPDWR. The EPA is publishing Final Human Health Toxicity Assessments for PFOA and PFOS (USEPA, 2024d; USEPA, 2024c); these assessments consider hundreds of studies reporting adverse health effects that are associated with long-term exposure to PFOA and PFOS. Similarly, the agency has substantial information supporting NPDWR finalization for the four additional PFAS considered in this rulemaking (i.e., PFNA, PFHxS, HFPO-DA, and PFBS). See sections 4.3 and 5 of the EPA response in this *Response to Comments* document for information on the Hazard Index MCLG and MCLs, respectively. Please see the PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024) regarding the agency's other efforts to address PFAS pollution and exposure, including monitoring efforts conducted under the Fifth Unregulated Contaminant Monitoring Rule (UCMR 5) and ongoing human health toxicity or risk assessments under development by the various agency program offices.

4.3. MCLG Derivation for a PFAS Mixture (HI MCLG) and for Additional Individual PFAS

The EPA requested comment on the proposed general Hazard Index approach for MCLG derivation for a mixture of PFHxS, PFNA, HFPO-DA, and/or PFBS and whether the agency should consider individual MCLGs (and MCLs) for some or all of these PFAS.

Many commenters agreed with the EPA's scientific conclusions about the dose additivity of PFHxS, PFNA, HFPO-DA, and PFBS based on a common adverse health outcome instead of a common MOA as a health protective default assumption (please see section 4.3.1 of the EPA response in this *Response to Comments* document). Other commenters asserted that the EPA failed to establish that the four PFAS included in the Hazard Index (PFHxS, PFNA, HFPO-DA, and PFBS) are dose additive and questioned whether the EPA's approach was consistent with the recommendations of the EPA SAB and existing agency guidance (please see section 4.3.1 of the EPA response in this *Response to Comments* document).

Many commenters agreed with the EPA's approach to use the general Hazard Index MCLG approach for a mixture of PFHxS, PFNA, HFPO-DA, and/or PFBS (please see section 4.3.2 of the EPA response in this *Response to Comments* document). Other commenters asserted that the general Hazard Index was not justified, questioned the EPA's external peer review process, asserted that the EPA approach was inconsistent with its own guidance, disagreed with the use of

toxicity reference values based on different adverse effects for the four PFAS in the Hazard Index , and/or suggested other approaches to consider PFAS mixtures (please see section 4.3.2 of the EPA response in this *Response to Comments* document). Several commenters favored finalization of individual MCLGs (and MCLs) for some or all of the PFAS included in the proposed Hazard Index, with or without a Hazard Index approach to address mixtures of these PFAS (please see section 4.3.2 of the EPA response in this *Response to Comments* document).

Many commenters expressed support for the EPA's derivation of HRLs and HBWCs and use of best available peer-reviewed science, whereas others were critical of the agency's selection of toxicity reference values, body weight-adjusted drinking water intake rates (DWI-BWs), and/or relative source contributions (RSCs) (please see section 4.3.3 of the EPA response in this *Response to Comments* document). Some commenters supported the EPA's use of the final ATSDR minimal risk levels for PFHxS and PFNA as chronic toxicity reference values as best available, peer-reviewed science; other commenters criticized the EPA for using ATSDR minimal risk levels and asserted that these values are inappropriate for SDWA rulemaking (please see section 4.3.3 of the EPA response in this *Response to Comments* document).

Some commenters asserted that the human health toxicity reference values upon which the HRLs/HBWCs are based have too much uncertainty and are therefore inadequate to support a SDWA regulatory determination (please see section 4.3.3 of the EPA response in this *Response to Comments* document).

Some commenters opposed the EPA's application of a 20 percent RSC in the HRL/HBWC calculations and others disagreed with the DWI-BWs that the EPA used to calculate the HRLs/HBWCs.

Some commenters had questions or comments about the process for adding additional PFAS to the Hazard Index (please see section 4.3.5 of the EPA response in this *Response to Comments* document). Many commenters urged the EPA to consider making a determination to regulate for additional PFAS (in a mixture) or all PFAS as a class. A few commenters expressed concern that the EPA would add PFAS to the Hazard Index without undergoing regulatory determination and/or rulemaking process (please see section 4.3.5 of the EPA response in this *Response to Comments* document).

The EPA's responses to these issues as well as others expressed by individual commenters are described in further detail below.

4.3.1 Dose Additivity

Summary of Major Public Comments and EPA Responses

Many commenters supported the EPA's scientific conclusions about PFAS dose additivity and agreed that considering dose-additive effects is a health-protective approach. Many other commenters disagreed with the EPA's scientific conclusions regarding PFAS dose additivity and a few commenters questioned the agency's external peer-review process and whether the agency

sufficiently responded to SAB comments. For example, these commenters stated that the evidence base of PFAS mixture studies is too limited to support dose additivity for these four PFAS and recommended that the EPA re-evaluate its conclusion about dose additivity as new data become available. A few commenters stated that the EPA failed to adequately follow the SAB recommendation that "discussion of studies of toxicological interactions in PFAS mixtures in the EPA mixtures document be expanded to also include studies that do not indicate dose additivity and/or a common MOA [mode of action] for PFAS." A few commenters opposed the EPA's use of shared or similar health endpoints/outcomes rather than a shared MOA as a basis for assessing risks of PFAS mixtures. Some commenters questioned whether the EPA's approach to dose additivity for these four PFAS was consistent with agency guidance and practice. The EPA response to these issues, as well as others expressed by individual commenters, are described in further detail below.

PFAS dose additivity is well supported. Based on the administrative record for the final PFAS National Primary Drinking Water Regulation (NPDWR), there is substantial evidence that exposure to PFHxS, PFNA, HFPO-DA, and PFBS individually elicits similar health effects (but with differing potencies for effect(s)); that these four PFAS act in a dose additive manner when present in mixtures; and that exposure to mixtures of these PFAS may cause adverse health effects. Dose additivity means that when two or more chemicals (in this case, PFHxS, PFNA, HFPO-DA, and/or PFBS) exist in one mixture, the risk of adverse health effects following exposure to the mixture is equal to the sum of the individual doses or concentrations scaled for potency (USEPA, 2000b). Studies with PFAS and other classes of chemicals support the health-protective conclusion that toxicologically similar chemicals (i.e., those that elicit similar observed adverse effects following individual exposure, even if at different exposure levels) should be assumed to act in a dose-additive manner when present in a mixture unless data demonstrate otherwise. Experimental data demonstrate that PFAS elicit similar adverse health effects on several of the same biological systems and functions including thyroid hormone signaling, lipid synthesis and metabolism, development, and immune and liver function (USEPA, 2024c; see additional discussion below on "toxicological similarity"). Thus, exposure to these PFAS, at doses that individually would not likely result in adverse health effects, when combined in a mixture may pose health risks.

Numerous published studies across multiple chemical classes, biological effects, and study designs support a dose-additive mixture assessment approach for PFAS because they demonstrate that experimentally observed responses to exposure to PFAS mixtures and other chemical mixtures are consistent with modeled predictions of dose additivity (see the EPA's *Framework for Estimating Noncancer Health Risks Associated with Mixtures of Per- and Polyfluoroalkyl Substances* (PFAS) (hereafter "PFAS Mixtures Framework;" USEPA, 2024c)). Since the EPA's draft PFAS Mixtures Framework underwent SAB review in 2021–2022, new studies from the EPA and others have provided robust evidence of combined toxicity of PFAS in mixtures, corroborating and confirming earlier findings (e.g., Conley et al., 2022b; 2023; see USEPA (2024c) for additional examples). Additionally, the National Academies of Sciences, Engineering, and Medicine (NASEM, 2022) recently recommended that clinicians apply an

additive approach for evaluating patient levels of PFAS currently measured in the National Health and Nutrition Examination Survey (NHANES) in order to protect human health from additive effects from PFAS co-exposure.

Data from *in vivo* studies that rigorously tested accuracy of dose additivity, Integrated Addition (IA), and Response Additivity (RA) model predictions of mixtures with components that disrupted the same pathways (i.e., were toxicologically similar) demonstrated that dose additivity models provided predictions that were better than or equal to IA and RA predictions of the observed mixture effects (Section 3.2 in USEPA (2024c)). In some circumstances the different additivity models provide highly similar predictions of mixture effects and thus are essentially equally effective. In situations where the models provide very different predictions, experimental data has demonstrated that dose additivity-based models consistently provide more accurate predictions of observed mixture effects than RA or IA. This strongly supports the use of dose additivity as the default method for estimating mixture effects of compounds that are toxicologically similar. The National Academy of Sciences (NAS) conclusions on phthalates (and related chemicals) (NRC, 2008) and systematic reviews of the published literature (Boobis et al., 2011 and Martin et al., 2021; see also Section 3.2 in USEPA (2024c)) support dose additivity as the default model for estimating mixture effects in some circumstances, even when the mixtures included chemicals with diverse MOAs (but the same target organs/effects).

Systematic reviews of mixture studies with chemical classes other than PFAS also indicate that departures from dose additivity are uncommon and rarely exceed minor deviations (~2-fold) from predictions based on dose additivity (Boobis et al., 2011; Martin et al., 2021). Boobis et al. (2011) examined literature from 1990 to 2008 that discussed synergy in mammalian test systems, with an emphasis on "low dose" studies. They found that of the 11 available studies with synergy data that reported the magnitude of the difference between the dose-additive estimates of toxicity and observed toxicity, six studies reported magnitudes of synergy that were generally small, and the authors concluded that deviations from dose additivity at low doses were not common. Additionally, Martin et al. (2021) reviewed more than 1,200 mixture studies and concluded that there was little evidence for synergy (greater than additive effects) or antagonism (less than additive effects) among chemicals in mixtures, and that dose additivity should be considered as the default model. This supports the health-protective conclusion that mixtures of PFHxS, PFNA, HFPO-DA, and/or PFBS should be assumed to act in a dose-additive manner unless data demonstrate otherwise.

Although some available *in vitro* studies do not provide conclusive evidence of dose additivity for PFAS mixtures, their results also do not justify drawing a conclusion other than dose additivity. For example, a study on PFAS cytotoxicity in a human liver cell line (Ojo et al., 2020) reported synergistic (greater than additive) effects (i.e., the combined effect(s) of the mixture components is greater than the sum of their individual effects) of mixtures of perfluoroalkyl acids (PFAAs; a type of PFAS) compared to a dose addition model, but also reported evidence of less than additive (antagonistic) effects. Other *in vitro* studies that have assessed PFAS mixture-based effects do not report these results; that is, they do not offer strong evidence for synergistic

or antagonistic effects, particularly at environmentally relevant concentrations. For example, Wolf et al. (2014) evaluated *in vitro* PPARα activation and reported that effects seen following exposure to combinations of different PFAS were consistent with dose additivity in the lower tested concentration ranges. Wolf et al. (2014) also reported slightly greater than additive effects at higher test concentrations (approximately 500 parts per billion to over 800 parts per million); however, in environmental media such as drinking water, PFAS are not likely to occur at these higher concentrations (e.g., see USEPA, 2024j). Carr et al. (2013) reported slightly less than additive effects for *in vitro* PPARα activation of binary mixtures of PFAAs including PFOA, PFNA, PFOS, and PFHxS. Addicks et al. (2023) evaluated mRNA transcription in primary human liver spheroids exposed to seven different PFAS mixtures and found that all tested mixtures produced effects that were consistent with effects predicted using dose addition. To summarize, the available *in vitro* data do not support a conclusion other than dose additivity for PFAS mixtures.

Available *in vivo* data on this subject similarly support dose additivity. Two studies with PFAS mixtures in zebrafish reported no indications of synergy (Ding et al., 2013; Menger et al., 2020). Additionally, recent EPA Office of Research and Development (ORD) studies provide robust evidence that PFAS behave in a dose-additive manner (Conley et al., 2022b; 2023; Gray et al., 2024). For example, results of a developmental toxicity study of exposure to PFOA and PFOS mixtures in rats showed that the observed results for almost all tested endpoints were consistent with dose additivity (Conley et al., 2022b). Likewise, a rat developmental study of a PFAS mixture of PFOS, HFPO-DA, and Nafion byproduct 2 (an emerging polyfluoroethersulfonic acid compound recently detected in human serum (Kotlarz et al., 2020)) found that multiple tested endpoints in both parental females and offspring conformed to dose additivity and no endpoints demonstrated synergy (Conley et al., 2023).

Additionally, as described in the final PFAS Mixtures Framework (USEPA, 2024i), over the past two decades, many *in vivo* experimental animal studies have been published in which toxicity of chemical mixtures has been systematically evaluated (e.g., Altenburger et al., 2000; Conley et al., 2022b, 2023; Crofton et al., 2005; Gennings et al., 2004; Hass et al., 2017; Howdeshell et al., 2015; Kortenkamp and Haas, 2009; Martin et al., 2021; Moser et al., 2005, 2012; Rider et al., 2008; 2009; 2010; Walker et al., 2005). These studies span different chemical classes, proposed MOAs, and health outcomes, but they generally show that chemicals in mixtures typically act dose additively. Even when mixture components with different MOAs/adverse outcome pathways (AOPs) are combined, they induce toxic effects consistent with dose additivity (e.g., Rider et al., 2009). This concept was further articulated in the National Research Council's 2008 report *Phthalates and cumulative risk assessment: The tasks ahead* (NRC, 2008), wherein that expert panel provided significant evidence that mixture components that elicit similar adverse health effects individually will demonstrate dose additivity when combined in a mixture, regardless of similarity in MOA.

This evidence base supports the longstanding recommendation in EPA chemical mixtures guidance for dose additivity as a default approach for evaluation of mixture toxicity (USEPA,

1986; USEPA, 2000b). This position is further supported and articulated in the newly published EPA Risk Assessment Forum's *Advances in Dose Addition for Chemical Mixtures: A White Paper* (USEPA, 2023j). (See additional discussion below on "toxicological similarity").

Comments from the SAB on dose additivity of PFAS mixtures. Importantly, the EPA's conclusions regarding dose additivity of PFAS were supported by the SAB during its 2021–2022 review of the EPA's draft *Framework for Estimating Noncancer Health Risks Associated with Mixtures of Per- and Polyfluoroalkyl Substances*. The EPA directly asked the SAB for feedback on PFAS dose additivity as part of the SAB's review of technical materials supporting development of the PFAS MCLG and NPDWR. Specifically, the EPA asked the SAB to, "[p]lease comment on the appropriateness of this approach for a component-based mixture evaluation of PFAS under an assumption of dose additivity" (USEPA, 2022b). The SAB strongly supported the scientific soundness of this approach when evaluating PFAS and concurred that it was a health-protective conclusion. For example, the SAB said:

> "The SAB supports dose additivity based on a common outcome, instead of a common mode of action as a health protective default assumption and does not propose another default approach." (USEPA, 2022b)
>
> "…The information included in the draft framework supports the conclusion that toxicological interactions of chemical mixtures are frequently additive or close to additive. It also supports the conclusion that dose additivity is a public health protective assumption that typically does not underestimate the toxicity of a mixture..." (USEPA, 2022b)
>
> "The SAB Panel agrees with use of the default assumption of dose additivity when evaluating PFAS mixtures that have similar effects and concludes that this assumption is health protective." (USEPA, 2022b)
>
> "…dose additivity can provide an estimate of composite effects." (USEPA, 2022b)

While the SAB also noted that there remain some questions about PFAS interaction in mixtures (USEPA, 2022b), the available data justify an approach that accounts for PFAS dose additivity. As described above, studies that have assessed PFAS mixture-based effects do not provide support for a conclusion other than dose additivity (i.e., they do not offer strong evidence for synergistic/antagonistic effects) (USEPA, 2024i).

The four PFAS included in the Hazard Index MCLG are "toxicologically similar" because they elicit the same or similar adverse health effects. The EPA's approach is to evaluate risks from exposure to mixtures of PFAS based on similar adverse health effects (but with differing potencies for effect(s)) of the individual PFAS mixture components, rather than similar MOA. MOA describes key changes in cellular or molecular events that may cause functional or structural changes that lead to adverse health effects and can be a useful metric by which risk can be assessed. It is considered a key determinant of chemical toxicity, and chemicals can often be classified by their type of toxicity pathway(s) or MOA(s). PFAS are an emerging chemical class,

and MOA data are limited or entirely lacking for many PFAS. Although similarities among some PFAS have been shown at the level of molecular and cellular perturbations, no conserved MOAs have been identified across PFAS for noncancer health effects assessed thus far. Therefore, the EPA's approach for assessing risks of PFAS mixtures is based on the conclusion that PFAS that are "toxicologically similar"—that is, elicit the same or similar adverse health effects (but might have differing potencies for effect(s))—will produce dose-additive effects from co-exposures (see USEPA, 2024i).

Some commenters stated that the EPA did not provide sufficient evidence that the four PFAS included in the Hazard Index share key events or adverse outcomes. The EPA disagrees. Available epidemiological and animal toxicological data demonstrate that exposure to each of these four PFAS (PFHxS, PFNA, HFPO-DA, and PFBS) is associated with many of the same or similar adverse health endpoints and outcomes, and thus they are "toxicologically similar" (see Tables 1, 2, and 3 below). Further, these four PFAS are well-studied PFAS for which the EPA or ATSDR has developed human health assessments and toxicity reference values (i.e., RfDs, minimal risk levels). Available animal toxicological and/or epidemiological studies demonstrate that PFHxS, PFNA, HFPO-DA, and PFBS are documented to affect at least five (5) of the same major health outcomes: lipids, developmental, immune, endocrine, and hematologic (Table 1). Similarly, according to the 2023 Interagency PFAS Report to Congress (United States OSTP, 2023), available animal toxicological data show that PFHxS, PFNA, HFPO-DA, and PFBS significantly affect at least eight (8) of the same major health effect domains: body weight, respiratory, hepatic, renal, endocrine, immunological, reproductive, and developmental (Table 2). Furthermore, numerous *in vivo* and *in vitro* studies demonstrate that these four PFAS share many of the same health effects across diverse health outcome categories (e.g., developmental, immunological, and endocrine), and that they induce some of the same effects at the molecular level along biological pathways (USEPA, 2024h). Table 3 below shows specific endpoints shared across these four PFAS, including toxicologically relevant molecular perturbations (*in vitro*), and health effects (*in vivo*) from oral repeated-dose studies in rats and/or mice (note that this table is a summary of select studies for illustrative purposes and should not be construed to represent a systematic review or MOA analysis). Some commenters asserted that PPARα activation is not relevant to humans, but the EPA disagrees because although rodents do appear to be relatively more sensitive to peroxisome proliferators compared to humans, a large body of evidence supports the plausibility of PPAR-dependent MOAs in organ toxicity(ies) across species (for review, see Lai et al. (2004)). Further, in a mouse strain that expressed humanized PPARα, PFOA exposure resulted in dysregulation of genes controlling lipid homeostasis, increased liver mass, histopathological evidence of steatosis, and increased serum cholesterol levels in males and females (Schlezinger et al., 2020). Lastly, there are other shared molecular/cellular perturbations (e.g., CAR activation) across the four PFAS in addition to PPARα, and multiple shared adverse health effects (Table 3). In summary, there is substantial evidence that PFHxS, PFNA, HFPO-DA, and PFBS elicit many of the same or similar toxicological effects and thus are "toxicologically similar."

Table 1. Affected health outcomes in animal toxicological and/or epidemiological studies for the four PFAS included in the Hazard Index MCLG (adapted from Table 6-7 in USEPA, 2024e).				
Health Outcome	**HFPO-DA**	**PFNA**	**PFHxS**	**PFBS**

Background on concept of "toxicological similarity." This concept and application of dose additivity for "toxicologically similar components" in mixtures assessment is consistent with EPA mixtures guidance (USEPA, 1986; USEPA, 2000b) and the EPA Risk Assessment Forum's *Advances in Dose Addition for Chemical Mixtures: A White Paper* (USEPA, 2023j). Specifically, the EPA's *Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures* (USEPA, 2000b) notes that although the shared MOA metric for application of dose addition is optimal, MOA data are not always available and that toxicological similarity in the context of mixtures risk assessment can be based on adverse effects observed at the organ or system level (USEPA, 2000b). This concept is further described in the EPA Risk Assessment Forum's *Advances in Dose Addition for Chemical Mixtures: A White Paper* (USEPA, 2023j): "The primary criterion for choosing between dose addition and response addition methods is toxicological similarity among the chemicals in the mixture [(USEPA, 2000b)]. "Toxicological similarity" is used here as an overarching concept with a wide range of specificity across levels of biological organization, allowing similarity judgments to be tailored to both the specific goals of the mixture risk assessment and the availability of hazard and dose-response information across components." Unless there are available data that suggest deviation(s) from dose additivity, mixture chemicals that are "toxicologically similar" (e.g., same/similar effect or profile of effect[s], regardless of differences in potencies) prototypically behave dose additively. This concept is depicted in Figure 1 below, which shows that dose additivity is the logical default approach for "toxicologically similar" components and that component-based mixture assessment approaches including Hazard Index (HI), relative potency factor (RPF), and mixture-benchmark dose (Mixture-BMD) are options for mixture assessment in such cases. (Please see section 4.3.2 of this *Response to Comments* document for a summary of comments and responses related to the EPA's use of the general Hazard Index approach to derive an MCLG for mixtures of two or more of PFHxS, PFNA, HFPO-DA, and PFBS).

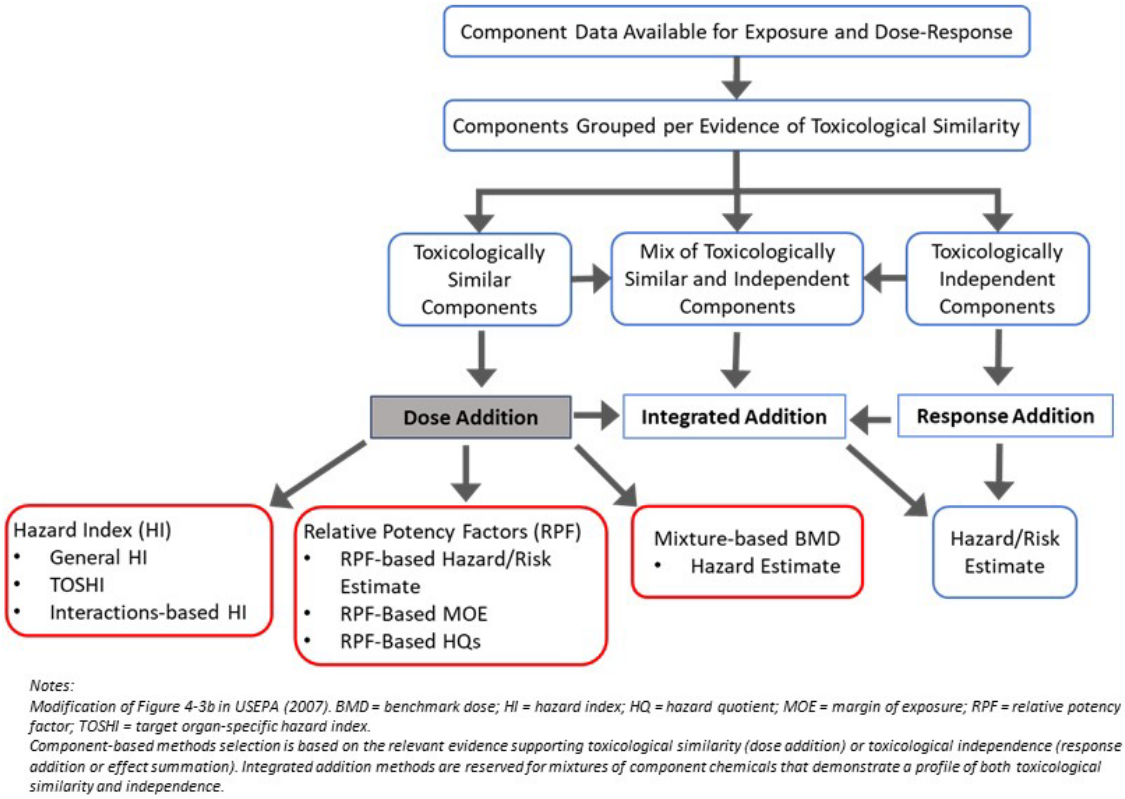

Figure 1. Flow chart for evaluating chemical mixtures using component-based additive methods. (Reproduction of Figure 2-1 from USEPA (2024i)).

Comments from the SAB on basing the concept of toxicological similarity for these PFAS on same/similar adverse effects in the absence of adequate MOA information. The SAB strongly supported the EPA's decision to focus on similarity of adverse health effects rather than similarity of MOA to assess risks of exposure to PFAS mixtures during its 2021–2022 review of the EPA's draft PFAS Mixtures Framework. Specifically, the EPA asked the SAB, "If common toxicity endpoint/health effect is not considered an optimal similarity domain for those PFAS with limited or no available MOA-type data, please provide specific alternative methodologies for integrating such chemicals into a component-based mixture evaluation(s)" (USEPA, 2022b). The SAB strongly supported the EPA's approach of using a similar toxicity endpoint/health effect instead of a common MOA as a default approach for evaluating mixtures of PFAS using dose additivity and did not recommend an alternative methodology. The SAB panel stated that: "The Panel agreed with use of a similar toxicity endpoint/health effect instead of a common MOA as a default approach for evaluating mixtures of PFAS. This approach makes sense because multiple physiological systems and multiple MOAs can contribute to a common health outcome. Human function is based on an integrated system of systems and not on single molecular changes as the sole drivers of any health outcome. The Panel concluded that rather than the common MOA, as presented in the EPA draft mixtures document, common physiological outcomes should be the

defining position" (USEPA, 2022b)."Furthermore, many PFAS, including the four used in the examples in the draft EPA mixtures document and others, elicit effects on multiple biological pathways that have common adverse outcomes in several biological systems (e.g., hepatic, thyroid, lipid synthesis and metabolism, developmental and immune toxicities)" (USEPA, 2022b).

Summary. The available scientific evidence supports the conclusion that PFAS that elicit similar adverse health effects following individual exposure (even if with differing potencies for effect(s)) should be assumed to act in a dose-additive manner when in a mixture unless data demonstrate otherwise. This means that individual PFAS, each at doses that are not anticipated to result in adverse health effects, when combined in a mixture may result in adverse health effects. (For a more complete discussion of the evidence supporting dose additivity as the default approach for assessing mixtures of PFAS, please see the final PFAS Mixtures Framework (USEPA, 2024i)). The EPA's conclusions regarding PFAS dose additivity were supported by the SAB during its review of the EPA's draft PFAS Mixtures Framework (USEPA, 2022b) and are consistent with longstanding agency chemical mixtures guidance (USEPA, 1986; 2000b) and a recent EPA white paper (USEPA, 2023j). The SAB also strongly supported the EPA's default assumption of dose additivity in the absence of other information and the EPA's approach of using similar toxicity endpoints/health effects instead of a common MOA for evaluating mixtures of PFAS (USEPA, 2022b). This approach of basing the concept of toxicological similarity on same/similar adverse effects in the absence of adequate MOA information is also consistent with the EPA's guidance (USEPA, 1986; 2000b) and a recent EPA white paper (USEPA, 2023j). The SAB also strongly supported the EPA's default assumption of dose additivity in the absence of other information and the EPA's approach of using similar toxicity endpoints/health effects instead of a common MOA for evaluating mixtures of PFAS (USEPA, 2022b). This approach of basing the concept of toxicological similarity on same/similar adverse effects in the absence of adequate MOA information is also consistent with the EPA's guidance (USEPA, 1986; 2000b) and the white paper (USEPA, 2023j). The EPA will consider new data and information that may become available on dose additivity and PFAS mixtures in the future.

Individual Public Comments and EPA Responses

Texas Commission on Environmental Quality (TCEQ) (Doc. #1632, SBC-044122)

Texas Commission on Environmental Quality (TCEQ) Comments on the United States Environmental Protection Agency's (EPA) Proposed Per- and Polyfluoroalkyl Substances National Primary Drinking Water Regulation

Docket ID Number EPA-HQ-OW-2022-0114

TCEQ provides the following comments on the proposed Per- and Polyfluoroalkyl Substances (PFAS) National Primary Drinking Water Regulation (NPDWR).

Hazard Index (HI)

The HI approach proposed for PFAS appears oversimplistic in assessing the potential for adverse health effects from four different PFAS with reference doses based on different critical effects and target organs of toxicity. An HI approach to evaluating risks from multiple chemicals involves considering the risk from each of the chemicals individually to derive a hazard quotient (HQ) for each, which is the concentration measured in drinking water/health-based water concentration, and then adding the HQs together to generate an HI for the chemical group. For this to be an appropriate method for determining risk from multiple chemicals, the dose of each chemical has to have an additive effect on a biological pathway, which is a mode of action (MOA), that contributes to effects in the same target organs. If the chemicals affect different biological pathways, then they will not have additive effects when a person is exposed to more than one of the chemicals at the same time.

The critical effect (i.e., the effect that occurs at the lowest exposure concentration) for the four PFAS are:

• Perfluorohexane sulfonic acid (PFHxS): Thyroid follicular epithelial hypertrophy/ hyperplasia in parental male rats;

• Hexafluoropropylene oxide dimer acid (HFPO-DA, GenX): Liver effects in female mice;

• Perfluorobutane sulfonic acid (PFBS): Decreased serum total thyroxine in newborn mice; and

• Perfluorononanoic acid (PFNA): Decreased body weight gain and delayed eye opening, preputial separation, and vaginal opening in mouse offspring.

These are different target organs and likely involve different MOAs. EPA appears to be proposing an HI approach for these PFAS simply because it is a conservative screening approach for potential health risk rather than an approach that has been established as a scientifically defensible one for predicting effects from combined exposure to these PFAS based on a common MOA for target organ effects. EPA states,

"Consistent with advice from the [Science Advisory Board] SAB, EPA considers it an appropriately health protective approach to assume dose additivity for PFAS co-occurring in mixtures as they share similar profiles of health effect domains (e.g., liver, thyroid, developmental, etc.). . . . To protect against the potential for dose additive health impacts from likely multi-chemical exposures of PFHxS, HFPO-DA, PFNA, and PFBS when they occur as mixtures in drinking water, the Agency is proposing to use the HI approach." [FN1: 88 Fed. Reg. 18638, 18668 (Mar. 29, 2023) (emphasis added).]

Thus, since these PFAS have several effects in common, dose additivity is simply being assumed because it is conservative, instead of EPA providing a scientifically defensible assessment that is based on the same shared MOA for a given target organ for the four PFAS. Although EPA states that dose additivity is the default assumption when considering effects seen with mixtures, [FN2: See, EPA, "PUBLIC REVIEW DRAFT: Framework for Estimating Noncancer Health Risks Associated with Mixture of Per- and Polyfluoroalkyl Substances (PFAS)," at 22, EPA Document

No. EPA-822-P-23-003 (Mar. 2023).] the following EPA statement confirms relaxation of this scientific standard,

"[T]he HI is used here as a decision aid, and determination of dose additivity among chemicals is relaxed from the level of common MOA to common target organ(s)/health outcome(s)." [FN3: 88 Fed. Reg. 18638, 18668 (Mar. 29, 2023) (emphasis added)]

EPA has stated that it proposes using the HI method because of concern regarding the potential dose additivity of the four PFAS,

"[W]hile EPA recognized that regulating these PFAS with individual [maximum contaminant levels] MCLs and [maximum contaminant level goals] MCLGs might be simpler to implement for some states or operators, if EPA were to regulate these PFAS individually and not under the HI MCL approach, it would not provide equivalent protection against potential dose additive impacts for these PFAS, nor would it establish a framework to consider potential dose additive impacts for future PFAS components or groups as EPA develops a better understanding of the adverse health effects of other PFAS." [FN4: 88 Fed. Reg. 18638, 18671 (Mar. 29, 2023).]

However, EPA should only evaluate dose additive effects when it has been scientifically demonstrated to be appropriate (e.g., common MOAs for target organ effects), and should not establish an HI framework just for the sake of having one, without scientific demonstration that it is appropriate. Such a framework can be established when EPA has demonstrated that a group of PFAS causes target organ effects through a common MOA; it would be scientifically inappropriate to establish an HI framework prior to that point in time and apply it to a group of PFAS for which this demonstration has not been made.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-044837)

The Proposed Hazard Index is not Based on Health Effects in a Common Organ, Much Less Those Resulting from a Common Mode of Action

As described in the previous section, the HBWCs for the four PFAS included in the Agency's proposed HI MCL are derived from animal data reporting disparate health effects and target organs. While the HBWC for HFPO-DA is based on liver effects in adult mice, the value for PFHxS is derived from thyroid effects in adult rats. Although both the PFNA and PFBS are derived from effects in offspring of exposed mice, the endpoint for PFNA is body weight while that for PFBS is thyroid hormone levels. Although application of an HI is a common approach to assessing exposure to mixtures applied in the context of CERCLA remedial investigations and risk assessments, it assumes that there is a common response to exposure to the individual substances in the mixture such that the responses can be added together. EPA has not established that there is common response to exposure to the four PFAS. in fact, there is compelling scientific evidence instead against any common mode of action among these four chemicals.

In describing its conclusion that dose addition can be applied to evaluating mixtures of these four PFAS, EPA indicates that "it is considered a reasonable health-protective assumption that PFAS which can be demonstrated to share one or more KEs or adverse outcomes will produce dose-additive effects from co-exposure." [FN142: USEPA. Framework for Estimating Noncancer Health Risks Associated with Mixtures of Per- and Polyfluoroalkyl Substances (PFAS). Public Review Draft. EPA-822-P-23-003. Office of Water/Office of Research and Development (2023). (USEPA PFAS Mixtures Framework)] However, the Agency has not provided evidence to suggest that the four PFAS included in its HI approach share KEs or adverse outcomes. As described above, and as noted by the Agency, moreover, the most commonly reported molecular initiating event (MIE) reported in laboratory studies - activation of PPARα - is a rodent-specific response of limited relevance to humans. [FN143: Hall et al. 2012.] Another common response in rodents – reduction in circulating thyroid hormone concentrations – is not viewed by NAS as an adverse effect due to quantitative differences between rodents and humans. [FN144: NRC 2015.] Despite reaching the conclusion, that "there is potential for disparate MIEs in PFAS related adverse outcome pathways (AOPs) and there is a lack of mechanistic characterization for most PFAS-mediated effects," [FN145: USEPA PFAS Mixtures Framework, at 32.] EPA still maintains that dose addition is a reasonable assumption.

This conclusion contrasts sharply with EPA guidance for identifying evidence of toxicologic similarity in analyzing mixtures. In its 2000 mixtures guidance, the Agency identifies the following types of evidence for assessing toxicologic similarity (in order of most to least informative) -

• Identical or similar toxicodynamics,

• Shared syndrome,

• Shared apical outcome,

• Effect on the same target organ,

• Structural similarity, and

• Similarly shaped dose response curves in comparable toxicity studies. [FN146: USEPA. Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures. EPA/630/R- 00/002. Risk Assessment Forum (2000). (USEPA Supplementary Mixtures Guidance)]

Aside from limited structural similarity, EPA's MCL proposal fails to offer substantive evidence from this hierarchical list to support a conclusion of toxicologic similarity. There are currently less than a dozen published whole mixture or binary component toxicity studies with PFAS. [FN147: Goodrum PE et al. Application of a framework for grouping and mixtures toxicity assessment of PFAS: a closer examination of dose-additivity approaches. Toxicol Sci 179(2):262-278 (2021).] These studies suggest that dose-additivity assumptions for PFAS are not yet supported by the available whole mixture toxicity data.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-052931)

The PFAS Mixtures Framework places considerable weight on the results of the 28-day studies of perfluoroalkyl carboxylates and sulfonates conducted by NTP. [FN148: NTP TR-096; NTP Technical Report on the Toxicity Studies of Perfluoroalkyl Carboxylates (Perfluorohexanoic Acid, Perfluorooctanoic acid, Perfluorononanoic Acid, and Perfluorodecanoic Acid) Administered by Gavage to Sprague Dawley (HSD:Sprague Dawley SD) Rats. Toxicity Report 97 (2019). (NTP TR-097)] In particular, the Agency notes the "rigorous exposure characterization and multiple endpoints spanning MIEs, KEs, and AOPs." [FN149: USEPA PFAS Mixtures Framework, at 31.] Yet, neither EPA nor NTP identify the events or pathways common to the four PFAS that support toxicologic similarity or the proposed HI approach.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Dylan Pilger (Doc. #1546, SBC-042676)

The EPA must consider possible synergistic effects of PFAS and adjust monitoring guidelines accordingly.

My first recommendation is that the EPA consider possible synergistic effects of PFAS and adjust guidelines accordingly. Current estimates in the proposed rule use an additive model. However, a review article published in 2021 found that animal and cell culture studies suggested that certain PFAS mixtures (including PFOS, PFOA, PFNA, PFDA, PFHxS, and PFHxA), may interact synergistically (Ojo et al., 2021). For example, Ojo et al. found that, PFOS has been found to have a synergistic inhibitory effect (cytotoxicity) with PFNA, PFHxS, and PFHpA in HepG2 human liver cells (Ojo et al., 2020). Therefore, an additive model for water monitoring may be insufficient for determining the safety of consuming water contaminated with different PFAS. PFBA, PFBS, PFHpA, PFHxA, PFHxS, PFOA, PFOS, PFPeA, and PFPeS have all been discovered in well water in the Kunia region of Oʻahu, the most populated island in Hawaiʻi (Hawaii DOH, n.d.-c). The Hawaiʻi State Department of Health has also detected PFHpS and 6:2 FTS in addition to the 9 PFAS just listed in another well in Kunia (Hawaii DOH, n.d.-b). These and other PFAS have been detected in areas across Oʻahu (Hawaii DOH, n.d.-a). This has generated great concern among people in my community, myself included, and it is crucial that the agency get this right.

EPA Response: Please see section 4.3.1 of the EPA response in this *Response to Comments* document.

Oklahoma Department of Environmental Quality (DEQ) (Doc. #1616, SBC-043039)

DEQ recommends that EPA reevaluate the default assumption of dose additivity as additional data become available.

EPA is proposing to use a Hazard Index (HI) approach with mixtures of PFHxS, HFPO-DA and its ammonium salt, PFNA, and PFBS. Dose-additivity is assumed for regulated co-occurring PFAS. The Science Advisory Board (SAB) agreed with the use of the dose additivity default assumption when evaluating PFAS mixtures that have similar effects. SAB recommended that EPA reevaluate the default assumption of dose additivity as additional data become available. DEQ recommends that EPA act in accordance with this recommendation from SAB.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Aidan Cecchetti (Doc. #1640, SBC-044361)

• EPA requests comment on the merits and drawbacks of the target-specific HI or RPF approach. EPA requests comment on the derivation of the HBWCs for each of the four PFAS considered as part of the HI (pg. 18664 Federal Register Volume 88, Number 60).

o The commenters note that the manner in which the HI approach described in EPA's proposed rule was developed does not conform with the recommendations of the SAB. The SAB specified the following: "The SAB PFAS Review Panel supports dose additivity based on a common outcome, instead of a common MOA as a health protective default assumption and does not propose another default approach." Although the commenters support the use of an HI approach for regulating mixtures of the four proposed PFAS based on common toxicological endpoints, EPA developed HBWCs for the four PFAS based on different adverse health outcomes. For example, HBWCs for PFHxS and PFBS were developed based on toxic effects on the thyroid, the HBWC for HFPO-DA was based on impacts to the liver, and the HBWC for PFNA was developed based on adverse developmental effects. The commenters do not believe that the approach of using data from different toxicological endpoints to produce a regulatory limit on mixtures conforms with the recommendations of the SAB regarding additive toxicity. EPA must provide additional substantiation for the use of toxicity data for different health outcomes or should produce a HI approach based on HBWCs developed from the same toxicological endpoints.

o Moreover, the commenters are particularly concerned about the possible error in the Federal Register indicating that PFHxS exposure data may have been used to develop the HBWC for PFNA (e.g., "The HBWC for PFNA is derived using a chronic reference value based on an ATSDR intermediate-duration oral Minimal Risk Level, which was based on developmental effects seen in mice after oral PFHxS exposure (ATSDR, 2021).") The commenters recommend that EPA clarify whether this is an erratum.

EPA Response: The EPA disagrees with the comment that HBWCs based on different endpoints is inconsistent with the SAB recommendations regarding dose additivity. For the EPA

response to this comment, please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

In response to the comment about a possible error in the Federal Register: there is a typographical error in the Federal Register Notice. The HBWC for PFNA was derived using data for PFNA, not PFHxS. The text quoted by the commenter should read, "The HBWC for PFNA is derived using a chronic reference value based on an ATSDR intermediate-duration oral Minimal Risk Level, which was based on developmental effects seen in mice after oral PFNA exposure (ATSDR, 2021)."

Aidan Cecchetti (Doc. #1640, SBC-044360)

Additionally, although there is a lack of data on the modes of action (MOAs) for the toxicity observed for many PFAS, the commenters agree with the Science Advisory Board opinion that "physiological outcomes should be the defining position" in determinations of additive toxicity, rather than MOAs. The SAB provides compelling evidence that dose additivity is a reasonable assumption for mixtures of chemicals with common toxicological endpoints but different MOAs. EPA has presented adequate substantiation that these contaminants produce adverse effects on common toxicological endpoints, which suggests that mixtures of those contaminants are likely to produce compounded effects on those endpoints and that basing the NPDWR on the assumption of additive toxicity should be health protective. Specifically, EPA has identified that the PFAS they are proposing to regulate using the HI approach produce adverse health effects on the liver (PFHxS, HFPO-DA, and PFNA), thyroid (PFHxS and PFBS), kidneys (HFPO-DA and PFBS), immune system (HFPO-DA and PFNA), reproductive systems (HFPO-DA and PFNA), and on development (all proposed HI PFAS).

EPA Response: This commenter supports the EPA's conclusion about dose additivity.

New York State Department of Health (NYS DOH) (Doc. #1677, SBC-044962)

25. Proposed Hazard Index Approach: The proposed rule would implement a framework for regulating a mixture of additional PFAS in drinking water through a hazard index approach rather than chemical-specific maximum contaminant levels (MCLs). However, the proposed approach is a departure from traditional risk assessment methods. The toxicity values for the four PFAS in the hazard index approach are based on disparate toxic endpoints (i.e., thyroid effects for PFBS and PFHxS, developmental effects for PFNA, and liver effects for GenX). This deviates from guidance on the use of hazard indices provided in the US EPA Risk Assessment Guidance for Superfund (US EPA 1989) and the US EPA Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures (US EPA 2000), which indicate that the premise of the hazard index is dose additivity where the component chemicals of the mixture have similar toxic effects on the same organ or biological system. The US EPA (1989) guidance further states that "application of the hazard index equation to a number of compounds that are not expected to induce the same type of effects or that do not act by the same mechanism could

overestimate the potential for effects..." A recent panel of independent experts deliberated on the most scientifically justified method of grouping PFAS for the purposes of human health risk assessment and regulatory actions and concluded that grouping PFAS together without data supporting common MOA and potency is inappropriate (Anderson et al., 2022). This panel of experts agreed that the HI dose additivity assumption for PFAS may be appropriate for screening (i.e., to determine if no risk or if further analysis is needed), but the data gaps currently present result in a high degree of uncertainty.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Three Rivers Waterkeeper (3RWK) (Doc. #1689, SBC-044975)

IV. Addressing the cumulative impact of PFAS is necessary to adequately address PFAS pollution.

Although 3RWK ultimately hopes that those living in the United States will one day no longer have to fear PFAS exposure at all, we support the EPA's decision to assume dose-additivity where PFHxS, HFPO-DA and GenX chemicals, PFNA, and PFBS (the PFAS addressed other than PFOS and PFOA) co-occur. Like PFOS and PFOA, these other PFAS compounds have a range of associated adverse health effects. This includes potentially affecting the growth and learning of children, interfering with the body's natural hormones, and increasing the risk of cancer. [FN17: Perfluoroalkyl and Polyfluoroalkyl Substances (PFAS) Frequently Asked Questions, Agency for Toxic Substances and Disease Registry Division of Community Health Investigations, Aug. 22, 2017, https://deq.nc.gov/media/9604/download.] They are often found together, and their health effects overlap.

EPA Response: This commenter supports the EPA's approach.

New Jersey Department of Environmental Protection (NJDEP) (Doc. #1699, SBC-045018)

MCLGs for Mixtures of PFHxS, HFPO-DA, PFNA, and PFBS

EPA requested comments on the general Hazard Index (HI) approach for the mixture of four PFAS, and on the merits and drawbacks of the target organ specific HI or Relative Potency Factor (RFP) approach. NJDEP agrees that PFAS, including PFNA, PFHxS, PFBS, and HFPO-DA, cause similar toxicological effects and that it is reasonable to assume that dose additivity describes the toxicological interactions of these PFAS.

EPA Response: This commenter supports the EPA's approach.

New Jersey Department of Environmental Protection (NJDEP) (Doc. #1699, SBC-045020)

EPA requested comment on the derivation of the HBWCs for the four PFAS included in the HI. Of the four PFAS (PFNA, PFHxS, PFBS, HFPO-DA) included in the HI, NJDEP has reviewed

the basis for the toxicity factor only for HFPO-DA. As stated in NJDEP (2022), the NJDEP Division of Science and Research "has reviewed the basis of the USEPA (2021) RfD [Reference Dose] of 3 ng/kg/day and concluded that it is scientifically justified and health protective."

Further, EPA requested comments on whether the Health Based Water Concentrations (HBWCs) should instead be proposed as stand-alone MCLGs in addition to or in lieu of the mixture MCLG. Use of HBWCs as stand-alone MCLGs in lieu of the mixture MCLG would not account for additive toxicity when mixtures of these PFAS are present in drinking water. Use of the HBWCs as stand-alone MCLGs in addition to the mixture MCLG would have no practical impact, since an exceedance of the HBWC for a specific PFAS would result in an HI above 1.0 even if none of the other PFAS included in the HI are detected.

EPA Response: The EPA agrees that the reference dose for HFPO-DA is scientifically justified and health protective.

For the EPA response to the comment about stand-alone MCLGs for the four PFAS, please see section 4.3.2 of the EPA response in this *Response to Comments* document. The EPA disagrees that deriving individual MCLGs in addition to the Hazard Index MCLG would have no practical impact; for the EPA's discussion on the establishment of stand-alone standards in lieu of or in addition to the Hazard Index MCL, please see section 5.2 of the EPA response in this *Response to Comments* document.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-045899)

c. The dose additivity concept underpinning the Hazard Index approach is flawed because the underlying data already accounts for the co-occurrence of these chemicals

As discussed, EPA argues that the data support the co-occurrence of the four PFAS. In justifying the use of a dose-additive Hazard Index approach, EPA argues that it is a "reasonable health-protective assumption"[FN77: 88 Fed. Reg. at 18663.] because these PFAS have co-exposures. However, in each step of the derivation of the HBWC, EPA makes conservative assumptions that also account for the co- occurrence of these chemicals. For instance, despite the availability of information and data to inform a more realistic value, EPA chose the most conservative default value of 20% for the RSC. By combining multiple conservative assumptions, the Hazard Index approach is no longer tethered to actual data, which is not the best available science.

EPA Response: The commenter is incorrect in stating that the "underlying data already accounts for the co-occurrence of these chemicals." The toxicity assessments that serve as the foundations for the four HBWCs included in the Hazard Index MCLG do not consider chemical co-occurrence and are based on chemical-specific data (e.g., animal toxicology and/or epidemiology studies) for each of the four individual PFAS included in the Hazard Index. In developing the HBWCs, the EPA applied a chemical-specific RSC for each of the four PFAS to account for potential aggregate risk from exposures and exposure pathways other than oral ingestion of drinking water; that is, the RSC considers multiple exposure pathways from the

same chemical rather than co-occurrence of multiple PFAS. For more information, please see sections 4.3.1 and 4.3.3 of the EPA response in this *Response to Comments* document.

Protecting Our Water, Environment, and Ratepayers (POWER) (Doc. #1714, SBC-045940)

It is arbitrary to use a Hazard Index to group compounds that do not have similar harms.

EPA's decision to group PFHxS, HFPO-DA, PFNA, and PFBS in the proposed Hazard Index is arbitrary because EPA has failed to demonstrate, and instead merely assumes, that these compounds have a dose-additive effect. EPA explains that "a mixture of chemicals with similar apical effects should be assumed to also act in a dose additive manner unless data demonstrate otherwise." Here, the data provided by the EPA do not support, and in fact undermine, the assumption that the compounds are dose additive.

First, it is arbitrary to consider the dose-additive effects for PFHxS and PFNA because no Reference Dose has been finalized for these compounds. Because the level of harm caused to a specific body part has not been finalized, it is arbitrary to determine that there is an additive effect with the other compounds prior to this data getting finalized.

Even if the proposed effect is considered, asserting a dose-additive effect for PFHxS, HFPO-DA, PFNA, and PFBS is arbitrary because the compounds do not impact the same body parts. The finalized health advisories explain that PFBS causes thyroid issues and HFPO-DA has liver impacts. [FN23: Proposed Rule, 88 Fed. Reg. at 18644-45.] The interim findings assert that PFNA causes developmental delays and PFHxS causes thyroid issues. Although some of the harms overlap among some subsets of these four compounds, all of them do not overlap. Because there are substantial differences between thyroid and liver harms, it is arbitrary to consider all of these harms together and assume they are additive in the Health Index. The proposed rule asserts that it is considering a body-wide effect, but it has failed to point to a precedent where it has considered the effects of other compounds over the whole body rather than on an organ or biological system.

EPA Response: For the EPA response to comments on dose additivity, please see section 4.3.1 of this *Response to Comments* document. For the EPA response to comments on the toxicity reference values for PFNA and PFHxS, see section 4.3.3 of the EPA response in this *Response to Comments* document.

Wyoming Department of Environmental Quality (WDEQ) (Doc. #1716, SBC-044775)

2. EPA Should Reconsider the Hazard Index Approach/or PFHxS, GenX, PFNA, and PFBS
WDEQ recognizes that EPA's September 1996 Guidelines for the Health Risk Assessment of Chemical Mixtures state that "If sufficient data are not available on the effects of the chemical mixture of concern or a reasonably similar mixture, the proposed approach is to assume additivity." Moreover, as outlined in the preamble to the proposed regulations, EPA relayed that "If the Agency only established an individual MCLG, the Agency would not provide any

protection against dose-additivity from regulated co occurring PFAS." WDEQ also notes that the Science Advisory Board agreed "that the HI can be used as an indicator of potential health risk(s) associated with exposure to mixtures of PFAS." Finally, the in March 2023 Maximum Contaminant Level Goal (MCLG) Summary Document for a Mixture of Four Per- and Polvfluoroalkvl Substances (PFAS): HFPO-DA and its Ammonium Salt (also known as GenX Chemicals), PFBS, PFNA, and PFHxS, EPA describes that "The agency selected the HI approach for MCLG development because a HBWC for HFPO-DA, PFBS, PFNA, and PFHxS is available and can be calculated."

While helpful, these statements imply that EPA is proposing the HI for PFHxS, GenX, PFNA, and PFBS because they co-occur, HBWCs were available, and EPA wanted to protect against potential dose additivity. The rationale does not explain why, based on the similarity of human health effects, EPA selected PFHxS, GenX, PFNA, and PFBS for inclusion in the HI. This lack of an explanation is particularly concerning considering that Health Advisories have not been finalized for PFNA and PFHxS.

Considering the significance of the first proposed NPDW rule for PFAS and the potential costs incurred by affected PWSs and rate-payers, WDEQ notes that EPA's September 1996 Guidelines for the Health Risk Assessment of Chemical Mixtures also describe that "Dose addition for dissimilar effects does not have strong scientific support and if done, should be justified on a case by case basis in terms of biological plausibility," and "concerns with the use of interaction data on experimental mammals to assess interactions in humans is based on the increasing appreciation for systematic differences among species in response to individual chemicals. If systematic differences in toxic sensitivity to single chemicals exist among species, then it seems reasonable to suggest that the magnitude of toxicant interactions among species also may vary in a systematic manner." Finally, WDEQ notes that the HBWCs for PFNA and PFHxS are from the Agency for Toxic Substances and Disease Registry, which were developed for a different purpose than is being applied here.

Given that all the studies used to derive the HBWCs for PFHxS, GenX, PFNA, and PFBS were conducted in mice, a lack of any studies that evaluated dose additivity of these chemicals, and a lack of corresponding health effect data or dose additivity studies in humans, the uncertainties associated the health effects data appear to outweigh the benefits of implementing the HI as proposed.

EPA Response: For the EPA response to comments about dose additivity, please see section 4.3.1 of this *Response to Comments* document. For the EPA response to comments on the toxicity reference values for PFNA and PFHxS, see section 4.3.3 of the EPA response in this *Response to Comments* document. For the EPA response to the comment about inclusion of these particular four PFAS in the Hazard Index, see section 4.3.5 of the EPA response in this *Response to Comments* document.

In response to the comment about how HAs have not been finalized for PFNA or PFHxS: HAs are not a pre-requisite for an NPDWR under the SDWA. There is nothing in the statute or the

EPA's historical regulatory practice that suggests that the agency should delay regulation of a contaminant in order to develop a HA first.

Connecticut Department of Public Health (CT DPH) (Doc. #1745, SBC-045212)

USEPA should provide stronger evidence to support dose additivity of the four PFAS, which is the assumption the general HI approach based on. PFAS have some similar health effects, but they also differ more than just in potency. For example, the most sensitive health endpoints for both PFBS and PFHxS are thyroid while there is much less data indicating the same health effect of GenX and PFNA. Assumptions of PFAS additivity may vary by health endpoint (as shown in Conley et al. 2022a,b) and are not well supported by the limited available science in laboratory animals (Marques et al 2021) or in humans (Borghese et al 2020; Kim et al. 2018; Liu 2022; Preston 2020; Stratakis 2020). While additive effects have been demonstrated for certain PFAS and some specific outcomes in experimental in silico or in vitro studies, such effects were not confirmed by the first in vivo study to evaluate effects of perinatal exposure to a PFAS mixture. Marques et. al., 2022 reported that a PFAS mixture of PFOS, PFOA, and PFHxS had very distinct effects on mouse dams and pups when compared to a single compound treatment, and the effects varied by outcome. For example, the effect on liver weights from PFOA alone was analogous to the effects seen for the PFAS mixture (thus, not additive). Increases in liver triglycerides were seen for each of the three single PFAS treatments, but not for the mixture (thus, not additive, and suggestive of antagonism). The differential impacts of specific PFAS have also been observed in human studies. For example, in large prospective Canadian study that evaluated the associations between maternal first trimester serum plasma concentrations of PFOA, PFOS, and PFHxS and gestational hypertension (HTN) or preeclampsia, higher levels of PFHxS were associated with development of preeclampsia, but not with gestational HTN and neither PFOA nor PFOS were associated with either outcome. Mixtures were not specifically evaluated (Borghese et al., 2020). DPH is not aware of any animal or epidemiological studies that have evaluated the additivity of the four PFAS included in the HI approach. USEPA should also provide more discussion on the interaction (synergies vs. antagonism) of the PFAS in a mixture, as the type of interaction (antagonistic, additive, or synergistic) appears to vary across lower vs higher PFAS concentrations (Blake et al. 2022) and across different species (Dale et al 2022) and by type of outcome.

EPA Response: Please see section 4.3.1 of the EPA response in this *Response to Comments* document and the 'PFAS Dose Additivity' section (Section 3.4) in the EPA's PFAS Mixtures Framework (USEPA, 2024i). The EPA's PFAS Mixtures Framework describes additional recent published studies with PFAS mixtures which found that, *in vivo*, dose additivity is the more accurate model for predicting effects of mixtures. The Marques et al. (2021) study cited by the commenter is discussed in the EPA's PFAS Mixtures Framework document. The study has limitations (e.g., it did not address dose additivity vs. response additivity predictions, and in fact, the experimental design precluded any such calculation, and therefore the authors' conclusions of mixture interactions (e.g., synergy or antagonism) were speculative; see additional discussion in USEPA (2024i)). This study is discussed in the EPA's PFAS Mixtures

Framework document. The epidemiological studies cited by the commenter (Borghese et al., 2020; Kim et al., 2018; Liu, 2022; Preston, 2020; Stratakis et al., 2020) report associations between PFAS exposure and different effects, and some mention associations between effects and total PFAS concentration. Such epidemiological studies are interesting and important but are typically not useful for comparison of dose additivity vs. response additivity model predictions.

Additionally, the EPA notes that there are no published studies definitively showing synergy or antagonism of PFAS mixtures. Certainly, effects differ from species to species and type of outcome, but this does not refute that dose additivity should be the default model.

American Water Works Association (AWWA) (Doc. #1759, SBC-045600)

[In proposing this MCLG, EPA is making several key scientific determinations to support this decision:]

2. Co-exposure to a mixture of PFNA, PFHxS, HFPO-DA, and PFBS can lead to an aggregate health effect as a result of dose additivity, and

3. The dose additivity of PFAS can be applied through the hazard index with dissimilar health effects, or outcomes.

AWWA contracted with Ramboll Consulting U.S. to assist in reviewing the EPA's approach and to offer detailed recommendations to improve this work. Ramboll has provided a detailed letter with recommendations, which is included as part of Appendix A.

AWWA supports the agency's interest in taking a public health protective stance on PFAS. It cannot do so based on the assumption of dose additivity without sufficient evidence. There are numerous concerns regarding the agency's determination that these compounds co-occur and that their co-exposure has a dose-additive effect on dissimilar outcomes. Based on the information that EPA has currently provided and relied upon, EPA has not met the statutory or scientific requirements to make a positive regulatory determination for these substances individually or as a mixture.

EPA Response: Please see sections 4.3.1, 4.3.2, 6, and 3 of the EPA response in this *Response to Comments* document.

American Water Works Association (AWWA) (Doc. #1759, SBC-045605)

Additionally, the agency has failed to provide adequate information to support the proposed approach to apply the hazard index to these compounds using reference doses based on the compound-specific critical health outcome, not a similar health outcome. In review of the draft approach, the SAB provided EPA with support for the determination of "dose additivity based on a common outcome" while also noting that this was appropriate "instead of a common mode of action as a health protective default assumption" (SAB, 2022). Additionally, the support document for this MCLG states that "component-based approaches for assessing risks of PFAS

mixtures are focused on evaluation of similarity of toxicological endpoint/effect rather than similarity in MOA [mode of action]". The proposed approach is inconsistent with this statement and is contrary to the SAB recommendations.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Environmental Protection Network (EPN) (Doc. #1773, SBC-043857)

We further support EPA's selection of the relative source contribution and most sensitive person in calculating the health-based reference values for these four chemicals. We note that the revised PFAS Mixtures Framework provides strong support for the dose additivity of PFAS chemicals and the need for a HI approach.

EPA Response: This commenter supports the EPA's approach.

3M Company (Doc. #1774, SBC-045677)

ii. The hazard index approach is based entirely on unscientific assumptions of dose additivity

EPA's proposed general HI method is inconsistent with long-standing policy and science regarding chemical hazard additivity. As described below, EPA has not established that the HIPFAS share a mode of action (MoA) that is relevant for humans, which is required to regulate groups of chemicals. [FN45: See, e.g., (Anderson et al. 2022).] MoA information is critical to grouping PFAS and "[o]nly those PFAS that affect the same target organ/tissue/system should be grouped and assessed for dose additive or response additive approaches." [FN46: Id. at 5.] This is consistent with long-standing EPA guidance stating that multi-chemical cumulative non-cancer hazards should only be assessed for chemicals with RfDs that are based on an effect on the same target organ (USEPA 1986, 1989, 2000b.

EPA admits that the HI MCL lacks evidence of a common MoA. [FN47: See 88 FR 18668.] To the contrary, the reference value for PFHxS and the RfD for PFBS are based on different thyroid effects, the HFPO-DA RfD is based on a "constellation" of liver effects, and the PFNA reference value is based on changes to body weight and development. For PFHxS and PFBS, the same thyroid endpoints are not used as the critical effects – for PFHxS the critical effect is based on thyroid follicular epithelial hypertrophy/hyperplasia in parental male rats and for PFBS the critical effect is based on decreased serum total thyroxine in newborn mice after gestational exposure to the mother. These effects are likely occurring via different MoAs due to the different life-stages affected (parental versus offspring, respectively). EPA has also not established a shared MoA or considered relative potencies of the HI-PFAS. Because the HI-PFAS lack a common toxicity endpoint, summing potential hazards (as measured with a hazard quotient or HQ), contradicts long-standing EPA guidance and widely held scientific opinion.

These differences in target organs [FN48: A target organ is an organ in the body most affected by a specific substance.] and critical effects for the four HI-PFAS are precisely why EPA did not use

a target organ-specific HI approach and instead opted for the screening-level HI approach, despite its inability to accurately characterize the additivity of the four HI-PFAS. EPA guidance (USEPA 1989) recommends the use of the general HI approach as an initial screening to assess potential adverse effects and not for binding regulatory purposes. The approach assumes that simultaneous exposures to several chemicals occurring below their respective health-based thresholds could result in an adverse health effect, regardless of the chemicals' target organs or mechanisms of action. The HI is calculated as the sum of the ratios of each chemical's exposure relative to that chemical's respective health-based threshold. If the resulting general HI is less than 1, then an unacceptable hazard does not exist, and no further evaluation is needed. However, if the general HI exceeds 1, the guidance then recommends conducting a refined assessment by separating the HI evaluation by target organ and/or mechanism of action. EPA's proposed HI MCL omits the critical consideration for shared target organs and/or mechanism of action to determine potential hazard.

Because the four HI-PFAS do not share the same target organ, potential hazards calculated via the general HI method are not toxicologically accurate. EPA's proposed general HI method fails to use the target organ-specific RfDs in the most appropriate manner, resulting in a screening-level assessment when a refined target organ HI approach is available and is far more appropriate. [FN49: EPA wrongly refers to the general HI method as a more health protective indicator of risk and the target organ-specific HI approach as less health protective estimate of risk. Noncancer evaluations are based on threshold effects and, as a result, are either health protective or not. The contention that the general HI is "more" health protective stems from the misapplication of the long-standing approach for assessing the potential hazards associated with exposure to more than one noncarcinogen. The general HI method results in an inaccurate potential hazard calculation that unnecessarily increases uncertainty, reduces transparency, and hinders the risk communication process] This flaw results in inaccurate and overly conservative MCLs, combined with problematic risk communication due to their flawed scientific foundation and lack of transparency.

In short, EPA's reliance on the general HI method for PFHxS, HFPO-DA, PFNA, and PFBS is contrary to long-standing practices employed in human health risk assessments, well established and scientifically sound principles of toxicology, and EPA guidance. Further, the proposed general HI approach cannot be claimed as a more health protective method. Rather, it is an inaccurate method for assessing exposures and risks to compounds with different toxicological endpoints, and because of the method's inaccuracy, cannot be used to determine health protectiveness or margin of safety. Considering these fundamental shortcomings, the use of the general HI method in the proposed NPDWR is arbitrary.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

The Chemours Company FC, LLC (Doc. #1845, SBC-046062)

1 EPA's justification for dose additivity of PFAS is inadequate; the weight of evidence from mixture studies is limited and does not support the assumption of dose additivity for these four PFAS.

In EPA's draft MCLG Summary Document for HFPO-DA, PFBS, PFNA, and PFHxS, the EPA cites findings from Conley et al. (2022) as a basis for their dose additivity assumption for these four PFAS (EPA 2023a). However, as stated in EPA's draft PFAS Mixtures Framework, "Limited work has been conducted on combined exposure to PFAS in experimental systems either in vitro or in vivo" (EPA 2023b). In fact, according to EPA (2023b), the Conley et al. (2022) study is the only published mammalian in vivo study available in the scientific peer-reviewed literature that has conducted mixture model-based analyses for PFAS. Further, data from Conley et al. (2022) are limited to two long-chain PFAS - specifically, PFOA and PFOS (individual and combined) effects in maternal and neonatal rats following exposure to relatively high dose levels. Notably, Conley et al. (2022) did not evaluate the four specific PFAS included in the HI MCLG.

In the draft PFAS Mixtures Framework, EPA mentions three other mammalian in vivo toxicity studies that have evaluated exposure to multiple PFAS, but notes that "these studies did not include individual PFAS dose response data or conduct any mixture model- based analyses, so it is not possible to ascertain if the mixtures behaved in a DA [dose additive] or RA [response additive] manner, or if interactions occurred" (EPA 2023b).

In addition, EPA (2023b) recognizes that only a "few in vitro studies have directly assessed the mixture-based effects of combined PFAS exposures," with in vitro studies reporting less than additive effects (Carr et al. 2013, Menger et al. 2020), effects consistent with dose additivity at low exposure concentrations (Wolf et al. 2014, Nielsen et al. 2022), synergistic and antagonistic effects (Ojo et al. 2020), or a mixture of interactive effects (Ding et al. 2013). Despite these inconsistent findings in vitro, EPA concluded evidence "for combined in vitro exposure to PFAAs [perfluorinated alkyl acids] demonstrate results that are either consistent with or have relatively minor deviations from predictions based on concentration additive models" (EPA 2023b). Importantly, EPA never defined "relatively minor" nor did it demonstrate that such deviations would not have significant impact.

EPA's Science Advisory Board (SAB) was charged with reviewing the 2021 draft PFAS Mixtures Framework. The SAB recommended that "discussion of studies of toxicological interactions in PFAS mixtures in the EPA mixtures document be expanded to also include studies that do not indicate dose additivity and/or a common MOA [mode of action] for PFAS" to "increase transparency and characterization of the uncertainties associated with the assumption of dose additivity" (EPA 2023c). Although a few studies were added in EPA's revised draft PFAS Mixtures Framework (EPA 2023b) that acknowledged non- additive interactions of PFAS, EPA failed to conduct a complete systematic review as part of its evaluation of the evidence base for PFAS mixtures to determine whether the weight of evidence supports dose additivity for these four PFAS. As a result, EPA failed to include several additional studies in its 2023 revised draft PFAS Mixtures Framework – specifically, EPA failed to include a number of in vitro studies demonstrating a lack of support for additivity of PFAS (Bjork et al. 2021, Fey et al. 2022, Hu et

al. 2014, Kjeldsen and Bonefeld-Jorgensen 2013). Therefore, based on the available studies examining PFAS mixtures, the overall weight of evidence does not support dose additivity for PFAS.

For the HI approach in the assessment of PFAS mixtures, EPA discusses dioxin-like chemicals (DLCs) and the toxic equivalence factor (TEF) approach as an example of a mixtures approach in the draft PFAS Mixtures Framework (EPA 2023b). However, there are important distinctions between DLCs and the four PFAS included in the proposed HI MCLG. Most notably, there are many toxicity studies specific to mixtures of DLCs. For example, a PubMed search of "(dioxin-like compounds and mixture) AND (toxicity)" yields 146 results. These results include a comprehensive mixtures study with a variety of DLCs conducted by the National Toxicology Program. Based on the extensive body of evidence, it was concluded that the results are consistent with the TEF approach and reflect dose additivity (Van den Berg et al. 2006, Walker et al. 2005).

Interestingly, despite the substantially larger body of evidence supporting dose additivity, and a common mode of action, for DLCs, EPA has only promulgated an MCL for a single DLC – specifically TCDD. There is no mixtures-based MCL for DLCs. While EPA could claim that the expectation is that utilities will calculate a total TEQ concentration that reflects detected concentrations of each DLC times its TEF, Van den Berg et al. (2006) (referenced in the PFAS Mixtures Framework) makes it clear that it is inappropriate to apply the TEFs to abiotic media, stating the following:

The expert panel emphasized that correct application of the present TEF scheme (see Table 1) and TEQ methodology in human risk assessment is only intended for estimating exposure to dioxin-like chemicals from consumption of food products, breast milk, etc. This limitation is derived from the fact that those REP studies that have been considered most relevant for the determination of the present TEFs are largely based on oral intake studies, often through the diet.

EPA Response: Please see section 4.3.1 of the EPA response in this *Response to Comments* document and 'Dose Additivity for PFAS' (Section 3) in the EPA's PFAS Mixtures Framework (USEPA, 2024i).

Regarding the comment on the need to define "relatively minor" deviations from dose additivity, this statement in EPA's PFAS Mixtures Framework (USEPA, 2024i) characterizes the findings of several *in vitro* studies which found that departures from dose additivity are uncommon and rarely exceed ~2- to 3-fold from predictions based on dose additivity. Such deviations in an experimental study are within the range of between-study variance that is expected for these types of *in vitro* and *in vivo* study designs in the literature (i.e., if an experimental mixture study was repeated multiple times, the observed mixture data would typically be expected to deviate ~2- to 4-fold greater than or less than the additivity prediction). This low-level deviation (~2- to 4-fold) from predictions based on dose additivity has been evaluated and described in several robust literature evaluation efforts across many chemical classes and study designs (see Boobis et al. (2011), Cedergreen et al. (2014), and Martin et al. (2021)) and thus the weight of evidence is

strongly in favor of dose additivity. Further, it has been determined that chemical mixture deviations from dose additivity most commonly occur at the highest experimental exposure concentrations, far exceeding those observed in human or environmental sampling data.

With respect to the SAB's recommendation to expand discussion of studies of toxicological interactions in PFAS mixtures, the EPA did update the PFAS Mixtures Framework to include the studies indicated in the SAB Report. The EPA also notes, however, that the mammalian PFAS mixture studies indicated in the SAB Report (Marques et al., 2021 and Roth et al., 2021) did not include individual chemical dose-response data or conduct any evaluation of mixture model predictions (i.e., dose addition versus response addition) compared to observed mixture effects. Thus, conclusions of mixture interactions (e.g., synergy or antagonism) were speculative and not supported by data published in those papers. The EPA also notes that in Nielsen et al. (2022), the generalized concentration addition (GCA) model of additivity has been developed for use with *in vitro* data that clearly identify full versus partial receptor activity (i.e., agonism or antagonism); however, there are no available data supporting the use of this model in estimating the *in vivo* effects from mixtures exposure. Regarding PFAS mixture studies of zebrafish, it has been clearly reported that fish peroxisome proliferator-activated receptors have low sequence homology to mammalian receptors and do not respond to many ligands that are active in mammalian systems; thus, the relevance of data reported from fish systems to the estimation of human health are unclear for PFAS. In regard to the additional *in vitro* mixture studies listed by the commenter, the Bjork et al. (2021) study inappropriately used a model of response addition (i.e., effect summation) instead of a dose addition model to evaluate additivity – thus the conclusion that the data did not fit additivity was in reference to response addition, not dose addition. The Fey et al. (2022) study was in zebrafish and used a non-human-relevant endpoint (swim bladder inflation), inappropriate dose-response modeling using a linear x-axis with widely spaced dose levels (log x-axis is appropriate), and the study does not report how mixture data analyses were conducted or what model of additivity was used for evaluation. Hu et al. (2014) evaluated binary and multi-chemical PFAS mixtures in vitro using a cell line that was erroneously identified as fetal liver but is now known to be HeLa cell-derived. That study reported non-monotonic J-shaped dose-response curves that included cell proliferation followed by cell death with disparate degrees of proliferation across the individual PFAS studied. The mixture models employed were not intended for use with component chemicals that display disparate maximum and minimum effect levels. Despite the difference in response functions, the observed mixture effects for cell death were well predicted using dose addition-based approaches (observed less than 2-fold different from predicted). Observed cell proliferation deviated from predictions; however, this was due to the discrepancy of effect magnitude across the component PFAS in the mixtures. In summary, there is limited information on PFAS mixture effects, but available high-quality published studies support dose additivity, as do multiple extensive literature analyses of mixtures of other classes of chemicals (see discussion in USEPA, 2024i).

Regarding the comment about application of toxicity equivalence factors (TEFs), which is a specialized form of relative potency factors (RPFs), 2,3,7,8-TCDD (referred to as 'dioxin') and associated dioxin-like compounds (DLCs) benefit from ample MOA data that demonstrate that

they all act through the same aryl hydrocarbon receptor (AhR) pathway to induce toxicity. This type of MOA information is not available for the vast majority of PFAS. Therefore, as described in section 4.3.1 of the EPA response in this *Response to Comments* document, the EPA's approach is to evaluate risks from exposure to mixtures of PFAS based on the fact that these PFAS elicit the same or similar adverse health effects (but may have differing potencies for effect(s)), an approach supported by the SAB and by EPA guidance.

The Chemours Company FC, LLC (Doc. #1845, SBC-046058)

Executive Summary

EPA's proposed maximum contaminant level goal (MCLG) for HFPO-DA, PFBS, PFNA, and PFHxS is based on a hazard index (HI) approach that assumes dose additivity for these four PFAS. In this proposed HI approach, a hazard quotient (HQ) is calculated as the ratio of exposure (i.e., measured drinking water concentration) to a health-based water concentration (HBWC) for each of the four PFAS. HQs for each of the four PFAS are then summed to yield the HI of the PFAS mixture. According to EPA, "a mixture HI exceeding indicates potential risk for a given environmental medium or site" (EPA 2023a). The following points represent key shortcomings in EPA's proposed HI MCLG for HFPO-DA, PFBS, PFNA, and PFHxS.

1) EPA's justification for dose additivity of PFAS is inadequate; the weight of evidence from mixture studies is limited and does not support the assumption of dose additivity for these four PFAS.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Lakewood Water District (LWD) (Doc. #1574, SBC-042754)

Hazard Index Approach is Flawed

The proposed Hazard Index (HI) approach is fundamentally flawed. Under the proposed HI approach, a water system could document that all four constituents of the Hazard Index are below the Health Based Water Concentrations (HBWCs) and still be characterized as hazardous. In fact, EPA shared this very scenario during several webinars with Example 2 of the HI calculations.

In EPA's Example 2, all four constituents are below the HBWC, yet the result was a HI above 1. This does not make sense. The HI concept should be significantly revised or discarded.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Lehigh County Authority (LCA) (Doc. #1600, SBC-042808)

2. Diversity of Health Impacts – The four PFAS compounds included in the Hazard Index have different health effects, including impacts on the liver, growth and development, hormones, kidney, immune system, lipid levels, nervous system, reproduction, and cancer. It is unclear how these health effects are related to each other, if at all. Therefore, it is unclear how combining them into a single Hazard Index will be protective of public health.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

City of Allentown and Lehigh County Authority (LCA), Pennsylvania (Doc. #1667, SBC-043674)

[The treatment of these compounds in the proposed regulation is problematic for several reasons:]

3. Diversity of Health Impacts – The four PFAS compounds included in the Hazard Index have different health effects, including impacts on the liver, growth and development, hormones, kidney, immune system, lipid levels, nervous system, reproduction, and cancer. It is unclear how these health effects are related to each other, if at all. Therefore, it is unclear how combining them into a single Hazard Index will be protective of public health.

Orange County Water District (OCWD), California (Doc. #1634, SBC-043238)

Furthermore, EPA should address additional concerns raised by AWWA regarding the legality and scientific validity of the Hazard Index approach to regulate a chemical mixture under the SDWA before finalizing the rule.

EPA Response: Please see sections 4.3.1, 4.3.2, and 3 of the EPA response in this *Response to Comments* document.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-044020)

4. EPA requests comment on the general HI approach for the mixture of four PFAS.

a. The inclusion of all of these compounds together using the proposed Health Index is not appropriate for a number of reasons. First, because they each have very different health impacts and EPA has previously mentioned in other guidance that they would not include chemicals with different toxic effects in a cumulative risk assessment. This also increases the difficulty in communicating health effects language to our customers. Customers are also comfortable with the "MCL" terminology they have seen for years in their CCRs; adding yet another concept and definition for HI will add to the complexity of the CCR. There are other better standardized

approaches for including multiple parameters under a chemical "umbrella", such as VOCs, SOCs, and DBPs.

EPA Response: Please see sections 4.3.1, 4.3.2, and 1.2 of the EPA response in this *Response to Comments* document. Also, the mixture risk assessment methods and applications in the final NPDWR and PFAS Mixtures Framework are not "cumulative risk assessment;" cumulative risk assessment is much broader in terms of the integration across multiple exposure routes/scenarios, and often includes stressors other than chemicals (e.g., physical conditions; microbial risks; nutritional status; socioeconomic factors; etc.) (see the EPA's PFAS Mixtures Framework, USEPA, 2024i).

WaterPIO (Doc. #1624, SBC-043474)

A quick note on the Hazard Index. Organizations more versed in the science than us have broken down the weaknesses of applying the HI approach for the first time to drinking water. We will simply point out one irrefutable fact that, again, shows how the EPA wants public water systems to fail.

If water providers test for the four PFAS that make up the Hazard Index – PFNA, PFHxS, PFBS, and HFPO-DA (GenX) – and find they are under the health-based concentrations for each one of the four, they should be in the clear for a possible drinking water violation, right?

Wrong.

Public water systems could still find themselves in violation of the HI if the total for all four PFAS in a mixture is above 1.0. So, water providers could be in good stead with the EPA's health-based concentrations for every one of the four compounds that make up the HI and still end up with a Notice of Violation that will also wreck public confidence in their drinking water.

Public water systems, again, are being put in a position to fail.

Some, especially in the activist community, are saying, "Why not set the regulations as low as possible? We know these chemicals are bad at higher levels," and one can reasonably agree that their argument has merit. No one in public water that we know is happy with these compounds being found in our source and drinking waters.

But that's not how we set regulations in this country. There are other factors involved, especially because setting regulations at these levels and using an HI is untenable and creates situations where water providers will have to pass on the astronomical costs of treatment to their customers. This will result in many of the very people activists are saying they are trying to protect turning to water sources that are not safer or to unhealthy beverages that pose a greater risk.

EPA Response: Please see sections 4.3.1, 4.3.2, and 5 of the EPA response in this *Response to Comments* document.

Southwest Regional Water District (Doc. #1772, SBC-044728)

Additionally, the District does not agree with the approach of the Hazard Index. Under the proposed rule, a utility could be below the individual limit for the four substances included in this value but using this method could still exceed the limit of 1 for the final HI value. The health effects of these compounds are not the same and therefore combining all into one value leans very conservatively in regulating these substances. For this reason, we urge the USEPA to eliminate this part of the proposed rule.

Thank you again for the opportunity to comment on these proposed rules. Should the USEPA have additional questions, the District is available for discussion. My contact information is below.

Sincerely,

Sarah Affrunti

Regulatory Compliance & Safety Manager Southwest Regional Water District
affruntis@swwater.org

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Metropolitan Water District of Southern California (Doc. #1777, SBC-045434)

4. EPA should consider the consequences and impacts of using the proposed Hazard Index approach

EPA is proposing individual MCLs of 4.0 ppt for PFOA and PFOS, and a Hazard Index approach as the MCL for four other PFAS – PFHxS, GenX chemicals, PFNA, and PFBS. [FN18: 88 Fed. Reg. at 18638.] As currently written, EPA is setting the MCL for the latter four PFAS at a Hazard Index of 1. A running annual average Hazard Index greater than 1.0 is a violation of the proposed Hazard Index MCL. [FN19: EPA, Understanding the PFAS National Primary Drinking Water Proposal Hazard Index (Mar. 2023), click here, Link: https://www.epa.gov/system/files/documents/2023-03/How%20do%20I%20calculate%20the%20Hazard%20Index._3.14.23.pdf .] However, according to the online Hazard Index MCL calculation tool, only one of the four (PFHxS, GenX chemicals, PFNA, and PFBS) needs to be present to trigger the regulatory requirements. This essentially means that the Hazard Index is the de facto MCL for each constituent, without EPA conducting the full cost-benefit analysis for each of these constituents.

EPA Response: Please see sections 4.3.1, 4.3.2, and 13.8 of the EPA response in this *Response to Comments* document.

Ohio Water Utility Council (OWUC), Ohio American Water Works Association (OAWWA) (Doc. #1782, SBC-044723)

The Hazard Index calculation proposed in this rule is of additional concern to the OWUC. Under the proposed rule, a utility could be below the individual limit for the four substances included in Hazard Index, but using this method could still exceed the limit of 1 for the final HI value. The health effects of these compounds are not the same and therefore combining all into one value leans very conservatively in regulating these substances. For this reason, we urge the USEPA to eliminate this part of the proposed rule.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Greater Cincinnati Water Works (GCWW) (Doc. #1550, SBC-042695)

In addition to our concerns about the economic burden this regulation will place on our customers and the unrealistic compliance schedule, we also do not agree with the approach taken with the Hazard Index. Using this method, utilities can exceed the limit of 1 when all four of the compounds are well below their respective health reference values. Because the critical health effects are not the same for all the compounds included in the Hazard Index, using this additive approach is overly conservative. We believe USEPA should eliminate this component of the regulation.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Aqua America, an Essential Utilities Company (Doc. #1623, SBC-043076)

Additionally, the Agency has failed to provide adequate information to support the proposed approach to apply the hazard index to these compounds using PFAS-specific critical effects. In review of the draft approach, the Science Advisory Board (SAB) provided EPA with support for the determination of "dose additivity based on a common outcome" while also noting that this was appropriate "instead of a common mode of action as a health protective default assumption." Additionally, the support document for this MCLG states that "component-based approaches for assessing risks of PFAS mixtures are focused on evaluation of similarity of toxicological endpoint/effect rather than similarity in MOA [mode of action]." The proposed approach is consistent with this statement and is contrary to the SAB recommendations.

In addition, this approach conflicts with guidance on risk assessment for mixtures from the Agency itself and the ATSDR. ATSDR's Framework for Assessing Health Impacts of Multiple Chemicals and Other Stressors notes that the hazard index method is most appropriately "applied to components that cause the same effect by the same mechanism or mode of action" but "may be applied to components with different target organs as a screening measure." Additionally, ATSDR's Public Health Assessment Guidance Manual indicates that when "the health guideline for each contaminant is based on different target organs, health assessors will need to calculate a target-organ-specific HQ [hazard quotient] for each contaminant." In addition to ATSDR guidance, EPA's own guidance for risk assessment of mixtures clearly indicates that the use of

critical effects from multiple tissues in a hazard index is inappropriate, specifically noting that the index requires "similarity in target organ." In fact, the guidance states that "because the hazard index is tied to a specific effect, the underlying data should be on that effect." As part of this guidance, the Agency recommends that target organ toxicity doses as opposed to a critical effect dose, which is what is proposed in this action.

Aqua recommends that the EPA re-issue the preliminary determination for PFHxS, PFNA, HFPO-DA, and PFBS as a mixture and recommends that prior to re-issuing a preliminary determination for a mixture of PFAS work towards refining the proposed approach to align with guidance from federal agencies (including EPA), recommendations from the SAB, and through support from stakeholders.

EPA Response: The EPA's final regulatory determinations use the best available science and have been finalized consistent with the statutory requirements under SDWA. Please see sections 4.3.1, 4.3.2, and 3 of the EPA response in this *Response to Comments* document for further discussion.

Texas Commission on Environmental Quality (TCEQ) (Doc. #1632, SBC-044123)

EPA also uses an HI approach for remedial decisions at Federal Superfund sites, but in contrast to what is being proposed for the PFAS MCL, for remediation an HI greater than 1 is used as a screening level that may then be sorted by target organ and MOA. [FN5: See, EPA, "Risk Assessment Guidance for Superfund Human Health Evaluation Manual (Part A)," at 8-14 to 8-15, EPA Document No. EPA/540/1-89/002 (1989) (referred to as USEPA. 1989) (describing procedure for calculating the HI by effect and by mechanism of action). Briefly, if one of the effect-specific HIs exceeds a value of 1 (i.e., unity), consideration of the mechanism of action may be warranted. Segregation of HIs requires identification of the major effects of each chemical, including those seen at higher doses than the critical effect (e.g., the chemical may cause liver damage at a dose of 100 mg/kg-day and neurotoxicity at a dose of 250 mg/kgday). Major effect categories include neurotoxicity, developmental toxicity, reproductive toxicity, immunotoxicity, and adverse effects by target organ (i.e., hepatic, renal, respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, and dermal/ocular effects).] Sorting by target organ and MOA is a process more consistent with the further evaluation contemplated by the SAB when they stated,

"In general, the screening level Hazard Index (HI) approach, in which Reference Values (RfVs) for the mixture components are used regardless of the effect on which the RfVs are based, is appropriate for initial screening of whether exposure to a mixture of PFAS poses a potential risk that should be further evaluated." [FN6: EPA, "EPA Response to Final Science Advisory Board Recommendations (August 2022) on Four Draft Support Documents for the EPA's Proposed PFAS National Primary Drinking Water Regulation," at 56, Section II.S2.1, EPA Document No. EPA–822–D–23–001 (Mar. 2023) (referred to as USEPA. 2023f) (emphasis added).]

Therefore, EPA's proposed HI approach is not scientifically defensible because it ignores both MOA and target organ differences among the four PFAS, yet nevertheless triggers action at a value greater than unity (i.e., 1). An alternative to the proposed HI approach is to use target-organ-specific hazard indices (TOSHI), which provide somewhat better information for decision-making about PFAS, or other chemical, contamination in drinking water or other media. The SAB recognized the TOSHI approach as more robust than a screening HI approach that ignores MOA and target organ (e.g., the one proposed by EPA) when they state,

"The TOSHI approach necessitates endpoint/health effect-specific reference values, not just overall reference values. . . . The TOSHI approach presents additional robustness compared to the Screening Level HI given the identification of human health/toxicity values that are effect/endpoint specific. . . . The TOSHI approach may merit consideration to be classified as a higher tier method compared to the Screening Level HI method for decision making purposes. This may also reflect current and future practices amongst states and others." [FN7: Id. At 58, Section II. S2.5.]

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. Additionally, the text from *Risk Assessment Guidance for Superfund Human Health Evaluation Manual (Part A)* (USEPA, 1989) quoted by the commenter omits an important qualifier statement, which is that "Although higher exposure levels may be required to produce adverse health effects other than the critical effect, the RfD can be used as the toxicity value for each effect category as a conservative and simplifying step." This is a critical consideration supported by the EPA's guidance.

Aidan Cecchetti (Doc. #1640, SBC-044359)

• EPA requests comment on the general HI approach for the mixture of four PFAS (pg. 18655 Federal Register Volume 88, Number 60). EPA requests comment on its proposal of using an HI approach for PFHxS, HFPO-DA, PFNA, and PFBS, including whether it can be clearly implemented and achieves the goal of protecting against dose additive noncancer health effects (pg. 18666 Federal Register Volume 88, Number 60).

o The commenters agree with the EPA's decision to use an HI approach to regulate levels of PFHxS, HFPO-DA, PFNA, and PFBS. Due to the lack of toxicological data on PFAS mixtures to confirm the assumption of dose additivity, the commenters agree with the SAB's determination that "dose additivity can provide an estimate of composite effects" at the levels at which EPA is regulating the PFAS mixtures. Based on dose additivity data for other mixtures of contaminants, the commenters agree with SAB's suggestion that this approach is unlikely to underestimate the adverse health effects of contaminant mixtures and should therefore be health protective.

EPA Response: This commenter supports the EPA's approach.

NCASI (Doc. #1651, SBC-043227)

3.0 The Inappropriate Application of the Hazard Index Approach for Listed PFAS

In this rulemaking, EPA proposes a Hazard Index (HI) approach that substantially diverges from the intended justification and implementation of HI in standard human health risk assessment applications:

"An important aspect of the proposed 'general HI' approach is that it is based on the availability of a reference value regardless of the critical effect for each mixture component. Unlike a target organ specific Hazard Index which is typically based on either shared mode-of-action or shared health outcome of mixture components, the general HI is based on a non-cancer reference value (RfD or Minimal Risk Level) for the critical (usually the most sensitive) effect of each component."34 [FN3: USEPA. 2000a. Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures. EPA 630–R–00–002. Available on the internet at: https:// cfpub.epa.gov/ncea/risk/recordisplay. cfm?deid=20533.] [FN4: USEPA. 1989. Risk assessment guidance for Superfund. Vol. 1. Human Health Evaluation Manual (Part A). EPA/540/1–89/002.](pg. 18656)

An HI approach is only justified, in a toxicological sense, when two or more compounds elicit the same endpoint or act on the same biological mode of action in producing an adverse health effect that forms the basis of the health hazard for those substances. PFAS, as a group, includes thousands of substances with unique physio-chemical properties, unique fate and transport properties, and unique toxicological profiles. Broadly inclusive criteria are unlikely to produce standards or risk assessment approaches with a well characterized margin of safety or that accurately reflects the hazard posed by individual substances within the group. This has been evidenced in the scientific literature, even in studies that have evaluated PFAS of relatively similar chemical structure. As an example, Pizzurro et al. 2019 examined the toxicokinetics of several PFAS compounds and came to the following conclusions:

"Overall, our analysis provides one of the first syntheses of available empirical PFAS toxicokinetic data to facilitate interpreting human relevance of findings observed in animal studies and developing health-based criteria for PFAS from such studies. Our analysis highlighted several notable differences among the different PFAS regarding species and substance-specific tissue partitioning, half-life, and transfer to developing offspring via the placenta or lactation, as well as highlighted data gaps for certain substances….Lastly, the results of this analysis indicate that there are toxicokinetic differences among the different PFAS based on chain length, and these substances should not be regulated as a group without careful consideration of how the substance-specific toxicokinetics may impact potential toxicity, including differing specific target organ toxicity and overall body burden."5 [FN5: Pizzurro, Daniella M.; Seeley, Mara; Kerper, Laura E.; Beck, Barbara D. 2019. Interspecies differences in perfluoroalkyl substances (PFAS) toxicokinetics and application to health-based criteria. Regulatory Toxicology and Pharmacology 106 239–250.]

None of the listed substances under the HI approach in the proposed rulemaking are have RfDs based on the same critical effect, nor is there a link between a mode of action each substance

elicits that is related to all of the critical effects that form the basis of the individual RfDs. The EPA acknowledges the diversity of health outcomes exhibited from exposure to these listed PFAS:

"The adverse health effects observed following oral exposure to such PFAS are significant and diverse…"(pg. 18643)

A HI approach is not appropriate for compounds with different toxic modes of action and it's use in the proposed rulemaking is inconsistent with other EPA programs. EPA states that "the application of the HI approach under a regulatory purview is not novel," and EPA uses CERCLA as an example (pg. 18669). While the HI is not novel, in EPA's 2000 "Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures," EPA lays out three approaches to conducing risk assessments for mixtures, recognizing how the state of the science influences which approaches is appropriate. In the "Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures," an EPA Risk Assessment Forum Technical Panel, August 2000, further states that the "major concerns for the user are whether the available data are on components or whole mixtures, whether the data are composed of either similar components or similar mixtures that can be thought of as acting by similar toxicologic processes, and whether the data may be grouped by emissions source, chemical structure, or biologic activity." EPA, in the proposed rulemaking does not support that these four additional PFAS compounds act by similar toxicologic processes.

The Hazard Index (HI) approach requires confirmation of the fundamental assumption of dose additivity. Systemic toxicants should be confirmed as having the same mode of action prior to dose summation6 [FN6: USEPA 2000 Risk Assessment Guidance for Superfund (RAGS) (https://www.epa.gov/sites/default/files/201509/documents/rags_a.pdf]. The four PFAS species included in the proposed HI summation, PFNA, HFPO-DA, PFHxS, and PFBS, are dissimilar and do not seem to have confirmatory data that they adhere to the dose additivity model as they do not share critical effects as the basis for their individual RfDs. The Supplementary Guidance also explains that the "term additivity is used when the effect of the combination of chemicals can be estimated directly from the sum of the scaled exposure levels (dose addition) or of the responses (response addition) of the individual components." EPA's attempt to use additivity is not based on either of the approaches in the 2000 Guidance.

Further, EPA's additivity approach in the proposed rulemaking appears to assume conclusion on issues that EPA is still considering as to PFAS compounds in other programs. In the CERCLA ANPRM issued in April 2023, EPA is specifically soliciting feedback on whether future CERCLA action could group PFAS compounds, including on the basis of modes of toxicological action:

EPA is considering whether to initiate a future action that would potentially designate groups or categories of PFAS as hazardous substances. A group or category refers to a set of PFAS that share one or more similar characteristics. Characteristics of interest could include, but are not

limited to, chemical structure (e.g., carbon chain length, functional group), physical and chemical properties, mode of toxicological action, precursors or degradants, or co-occurrence.

EPA also gives an example of the TCSA Significant New User Rule (SNUR) where grouping was based on chemical structure.

In the TSCA program, EPA has developed Draft Principles for Cumulative Risk Assessment (CRA). In that document, EPA bases additivity on toxicological similarity: "Deciding, based on their toxicological similarity, which chemical substances to include in a cumulative chemical group that subsequently would be evaluated using dose additive models is an important element of a CRA." [FN7: Draft Principles for Cumulative Risk Assessment, EPA Document# EPA-740-P-23-001, Feb. 2023 United States Office of Chemical Safety and Environmental Protection Agency, Pollution Prevention, lines 458-460.]

These four additional PFAS are not toxicologically similar, so EPA grouping them under the MCL proposed rulemaking is inconsistent with how EPA would group chemicals under TSCA and CERCLA.

In light of the evidence that critical health endpoints for individual PFAS, including those listed under the HI approach in the proposed rulemaking, are unique and diverse the assumption of dose additivity is not valid and therefore the use of the Hazard Index as a risk management approach is not appropriate.

Feel free to contact me regarding these comments.

Respectfully submitted,

Giffe Johnson, PhD

Program Manager, Chemical Management and Health Effects

NCASI

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

<u>New York State Department of Health (NYS DOH) (Doc. #1677, SBC-044964)</u>

Grouping PFAS indiscriminately without considering toxic endpoint, mechanism of action or structural similarity is not necessarily the best precedent for EPA to take. We note that EPA's Science Advisory Board's (SAB) review of a mixtures framework for PFAS was in the context of the general hazard index approach (involving different reference value health endpoints) being an initial screening tool that would require further evaluation, rather than a regulatory tool for national drinking water standards (Final SAB Report, August 22, 2022 response to Charge Question #2, page 91). EPA needs to carefully evaluate the proposed hazard index approach both for scientific merit and regulatory precedent. There have been a variety of other PFAS grouping approaches taken in risk assessment and regulatory contexts including a proposed rulemaking

package in New York State in which PFAS were grouped on endpoint and structural grounds. We encourage EPA to reconsider how the critically important issue of PFAS mixtures should be addressed within a regulatory context.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Clean Air Council, et al. (Doc. #1731, SBC-043881)

b. The HI method proposed for PFHxS, HFPO–DA, PFNA, and PFBS is effective and better protects public health than individual MCLs.

The adverse health effects of these four compounds are well documented, as discussed for example in the proposed NPDWR [FN50: 88 Fed. Reg. 18638.]. However, unlike PFOA and PFOS, where their carcinogenic nature requires setting their MCLG at 0.0 ppt (the health-based goal, as opposed to the proposed enforceable 4.0 ppt MCI for PFOA and PFOS discussed in the previous sections), PFHxS, HFPO–DA, PFNA, and PFBS have not been classified as cancer-causing. As a result, there is some variability—which could be large—in the determination of their maximal safe level, as shown for example in the Table below:

[Table: see docket ID EPA-HQ-OW-2022-0114-1731]

Accordingly, Commenters ask that EPA continue reviewing data regarding the health effects of these compounds, and adjust the HBWC values as better understanding becomes available.

Addressing the additive effects of different PFAS is also crucial for protecting public health. As discussed in a recent EPA analysis, these compounds comply with EPA's definition of dose-additivity, which concludes that "PFOA and PFOS, as well as other PFAS with linear or branched alkyl or alkyl ether chains and sulfonic or carboxylic acid functional groups, share common toxicological impacts of exposure on multiple cellular receptors, tissues, life stages, and species (ATSDR, 2021; EFSA et al., 2018, 2020)." [FN54: EPA, Draft Framework for Estimating Noncancer Health Risks Associated with Mixtures of Per- and Polyfluoroalkyl Substances (PFAS) 23 (Nov. 2021), available at https://sab.epa.gov/ords/sab/f?p=100:18:16490947993:::RP,18:P18_ID:2601, (emphasis added).] Accounting for the adverse health effects of mixtures of these compounds is essential, in particular since the probability of co-occurrence is high. For example, in the Pennsylvania drinking water sampling study approximately 70% of samples containing PFNA also contained at least one other PFAs species that is not PFOA or PFOS.

Some states approached the issue of dose-additivity by requiring that the sum of several PFAS species be below a certain value. For example, Massachusetts set a maximum of 20 ppt for the sum of PFOS, PFOA, PFHxS, PFNA, PFHpA and PFDA [FN55: MassDEP, Per- and Polyfluoroalkyl Substances (PFAS), https://www.mass.gov/info-details/per-and-polyfluoroalkyl-substances-pfas#drinking-water-standards-and-health-information- (last visited May 24, 2023).] Using this approach, however, neglects the differences in health impacts of the compounds. For

example, as can be seen in the Table, 10 ppt of PFNA are clearly harmful to public health, although PFBS at these levels will not likely have a large impact.

Therefore, the methodology of HI proposed by the EPA is an optimization that accounts for both dose-additivity, and the individual hazard posed by each of the four PFAS compounds: Like an MCL, exceeding the HBWC for an individual species (which would lead to an HI >1) would require water treatment in the same way as would an individually set MCL. However, additivity is accounted for in samples where several compounds are present at values that are below the individual HBWC but where HI >1, which indicates harmful effects of the total PFAS exposure and would similarly require water treatment.

Commenters strongly support the HI approach; However, HBWC values should be reviewed and adjusted to reflect the evolving understanding of the effects of these compounds on human health. Also, as understanding of the adverse health effects of other PFAS species becomes more clear, these should be added to the HI.

EPA Response: This commenter supports the EPA's conclusion about dose additivity and use of the Hazard Index approach. For the EPA response to the comment asking that the EPA continue reviewing data regarding the health effects of these compounds and adjust the HBWC values as better understanding becomes available, please see sections 4.3.1 and 4.3.2 of this *Response to Comments* document. For the EPA response to comments on the addition of other PFAS to the Hazard Index, see section 4.3.5 of the EPA response in this *Response to Comments* document.

Florida Section American Water Works Association - Water Utility Council (FSAWWA WUC) (Doc. #1737, SBC-044492)

The Florida Water Sector does not support the EPA' s Hazard Index as a MCLG and MCL. This tool is being misapplied as a NPDWR. In addition, the rationale and framework is too complex to us yet alone for the communities we are privileged to serve. For example, the scale difference between the Health Based Water Concentration (HBWCs) for PFBS (2000 parts per trillion, ppt) and the other three compounds (9.0 ppt for PFHxS, 10.0 ppt for HFPO-DA; 10.0 ppt for PFNA) seems inappropriate. It is also our understanding from American Water Works Association, the health endpoints are not the same for each compound which EPA states in the proposed rule their Scientific Advisory Board advised them to be necessary (Executive Summary, paragraph 6).

EPA Response: For the EPA response to comments about toxicity reference values based on different endpoints for the four PFAS, please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. Please also see section 1.2 of the EPA response in this *Response to Comments* document.

American Water Works Association (AWWA) (Doc. #1759, SBC-045559)

Additionally, the agency's proposed drinking water standard for the mixture of PFHxS, PFNA, HFPO-DA, and PFBS poses several issues that must be addressed prior to further action. As discussed above, the underlying data to support a regulatory determination is insufficient and likely suggests that regulation does not represent meaningful opportunity to protect public health. The agency's approach to using a general hazard index with multiple health outcomes lacks support from risk assessment guidance and professionals (ATSDR, 2018; ATSDR, 2022; EPA, 1986; EPA, 2000; SAB, 2022).

EPA Response: For the EPA response to comments that the proposed regulation does not represent meaningful opportunity to protect public health, please see section 3 of this *Response to Comments* document. For the EPA response to comments about the use of a general Hazard Index based on different health outcomes, see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

American Water Works Association (AWWA) (Doc. #1759, SBC-045606)

In addition, ATSDR and EPA guidance on risk assessment for mixtures recommends against the use of a common mode of action when using a hazard index. ATSDR's Framework for Assessing Health Impacts of Multiple Chemicals and Other Stressors notes that the hazard index method is most appropriately "applied to components that cause the same effect by the same mechanism or mode of action" but "may be applied to components with different target organs as a screening measure" (ATSDR, 2018). ATSDR's Public Health Assessment Guidance Manual indicates that when "the health guideline for each contaminant is based on different target organs, health assessors will need to calculate a target-organ-specific HQ [hazard quotient] for each contaminant" (ATSDR, 2022). Both ATSDR guidance and EPA's own guidance for risk assessment of mixtures clearly indicates that the use of critical effects from multiple tissues in a hazard index is generally inappropriate, specifically noting that the index requires "similarity in target organ" (EPA, 1986). In fact, the guidance states that "because the hazard index is ed to a specific effect, the underlying data should be on that effect." As part of this guidance, the agency recommends that target organ toxicity doses as opposed to a critical effect dose, which is what is proposed in this action.

Detailed comments and recommendations on the proposed hazard index approach for PFNA, PFHxS, HFPO-DA, and PFBS were prepared for AWWA by Ramboll US Consulting and can be found in Appendix A of these comments.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

American Water Works Association (AWWA) (Doc. #1759, SBC-045593)

Equally importantly, EPA's proposed approach to using the general hazard index is significantly flawed and is not supported by federal agency guidance nor recommendations from the Science Advisory Board (SAB) (ATSDR, 2018; ATSDR, 2022; EPA, 1986; EPA, 2000; SAB, 2022),

which collectively recommend that a common health outcome should be used as the basis for a hazard index in this context.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-044826)

For the other four PFAS – HFPO-DA, PFHXS, PFNA, and PBFS – EPA proposes to establish health-based water concentrations (HBWCs) generated from studies in laboratory animal studies suggesting adverse effects in different target organs. The proposal to combine these disparate effects into a single HI assumes a common toxic endpoint and is inconsistent with Agency guidance and with accepted scientific practice, as well as the recommendations of peer reviewers. All of the values developed by EPA assume a relative source contribution (RSC) of 20 percent, despite the fact that PFOA, PFOS, PFHxS, and PFNA have been out of commerce for several years and available evidence suggests a significant decline in exposure.

EPA Response: For the EPA response to comments about a Hazard Index based on different adverse effects, please see sections 4.3.1 and 4.3.2 of this *Response to Comments* document. For the EPA response to comments about RSC derivation, please see section 4.3.3 of the EPA response in this *Response to Comments* document. Additionally, the commenter implied that the RSCs for PFOA, PFOS, PFHxS, and PFNA should not be 20 percent because these chemicals have been "out of commerce" for several years and evidence suggests a decline in exposure. The EPA disagrees. The unique physical and chemical properties that make some PFAS, including PFOA, PFOS, PFNA, and PFHxS, highly stable and resistant to degradation in the environment and human body, resulting in their colloquial name of "forever chemicals," indicates that exposure to these chemicals will continue regardless of their status of use in commerce. For example, PFOA and PFOS continue to be detected in environmental media (e.g., drinking water) as well as people's blood despite having been phased out of production years ago (the primary U.S. manufacturer of PFOS voluntarily phased out PFOS production by 2002 and in 2006; eight major PFOA manufacturers voluntarily agreed to phase out PFOA production by 2015).

The Chemours Company FC, LLC (Doc. #1845, SBC-046063)

2 The overall weight of the evidence does not support grouping these specific four PFAS.

The four PFAS in EPA's proposed HI MCLG consist of a mixture of short and long-chain carboxylated and sulfonated compounds. Recently, several research groups have demonstrated the importance of considering the chemical structures of PFAS when grouping PFAS together, as modes of action and toxicological profiles differ by chain length (i.e., short- versus long-chain) and functional groups (i.e., sulfonate or carboxylate) (Nielsen et al. 2022, Rericha et al. 2022, Goodrum et al. 2021, Colnot and Dekant 2022). Except for PFBS and PFHxS, the toxicity values developed for each PFAS in EPA's proposed HI MCLG are based on different endpoints (i.e.,

liver, thyroid or developmental effects). In addition, pharmacokinetic properties (e.g., serum elimination half-lives) and potential for bioaccumulation also differ between PFAS and should be considered when developing approaches for mixtures. For example, the serum and urine elimination half- lives for HFPO-DA in mammals are on the order of hours (Gannon et al. 2016), whereas the serum elimination half-life for PFBS in humans is on the order of days (Olsen et al. 2009) and urine elimination half-lives for PFHxS and PFNA are on the order of years (Zhang et al. 2013). Important toxicological differences exist between HFPO-DA, PFBS, PFNA, and PFHxS, therefore, application of EPA's general HI approach for these four PFAS is not appropriate based on the best available science.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. Additionally, in response to the commenter's assertion that pharmacokinetic properties should be considered, this is indeed accounted for in human health assessments and a given PFAS RfD does consider toxicokinetic differences. Specifically, toxicokinetic data such as clearance, plasma or serum half-life, and volume of distribution between experimental animals and humans are leveraged to calculate dosimetric adjustment factors (DAFs), which are used to adjust animal points of departure (PODs) to human equivalent PODs. These adjusted PODs are then used as the basis for RfD derivation. The four PFAS in the Hazard Index MCLG are "toxicologically similar" (see Tables 1, 2, and 3 and section 4.3.1 of the EPA response in this *Response to Comments* document).

GFL Environmental (Doc. #1648, SBC-043221)

Additional Technical Comments on the Proposed NPDWR

Based on our understanding of the HI approach as discussed with our consulting experts, regulating PFHxS, PFNA, PFBS, and GenX with this approach deviates from EPA's own standard practice for establishing MCLs and is not a scientifically sound approach for the following reasons:

• The HI approach is simplified and does not consider health effects on common organs. EPA's own risk assessment protocol (EPA, 2000) recommends summing only the chemical-specific hazards according to toxicological similarity (e.g., the same target organs or systems) because the toxicological effects associated with exposure to multiple chemicals, often through different exposure pathways, may not be additive.

• For health reference values, EPA relies on Health-Based Water Concentrations (HBWCs). EPA uses their Human Health Toxicity Assessments for GenX and PFBS but does not have published human health toxicity assessments for PFHxS and PFNA; EPA relies on Agency for Toxic Substances and Disease Registry (ATSDR) Minimum Risk Levels (MRLs) for these compounds. Per ATSDR, MRLs are screening levels and are not designed or intended to be used as public water standards (ATSDR, November 2018). EPA Human Health Toxicity Assessments have not been generated for PFHxS and PFNA and until they are, or more independent health hazard

information is adequately assessed by EPA, we propose that these chemicals should not be considered under the NPDWR.

• The HI approach is complex (i.e., it is not a value-to-value comparison) and will be difficult to communicate to the general public through publicly facing data portals.

EPA Response: For the EPA response to comments about the Hazard Index based on toxicity reference values for different adverse effects, please see section 4.3.2 of the EPA response in this *Response to Comments* document. For the EPA response to comments about the use of ATSDR minimal risk levels, please see section 4.3.3 of the EPA response in this *Response to Comments* document. For responses related to risk communication, see sections 1.2, 5.2.1, and 5.3.1 of the EPA response in this *Response to Comments* document.

Water Works Board of the City of Birmingham (BWWB) (Doc. #1602, SBC-043649)

5) Regulatory Unreasonableness and Continued Uncertainty

1. Hazard Index (HI) approach assumes that the impact of respective PFAS compounds relative to their relative disparate health effect endpoints (i.e., in this case: thyroid, liver, and developmental) are additive.

One limitation of the HI is that it does not consider the possibility of toxicological synergies or potentiation occurring as a result of multiple PFAS species being present in the sample at once. The HI is based on the assumption that "the dose response of multiple chemicals causing a common toxicological effect will follow dose addition models. Dose addition models assume that chemicals behave as if they were dilutions or concentrations of one another" (Price 2023). The HI is also unable to quantitatively predict the probability of specific adverse effects as all are combined into a single ratio (Price 2023).

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Pennsylvania Department of Environmental Protection (Doc. #1626, SBC-052945)

• In the document titled Maximum Contaminant Level Goal (MCLG) Summary Document for a Mixture of Four Per- and Polyfluoroalkyl Substances (PFAS): HFPO-DA and its Ammonium Salt (also known as GenX Chemicals), PFBS, PBNA, and PFHxS, EPA states that the HBWCs for the four PFAS included in the HI MCL are based on the following non-cancer health effects: liver effects for GenX, thyroid effects for PFBS, developmental effects for PFNA, and thyroid effects for PFHxS. DEP concedes that a combined MCL may be most effective for implementation for PFAS with non-cancer health effects, but questions making assumptions about additive effects based on different health endpoints. In the EPA Science Advisory Board's (SAB) Review of EPA's Analyses to Support EPA 's National Primary Drinking Water Rulemaking for PFAS, the SAB stated that when health endpoints of a group of compounds is similar, the HI is "a reasonable approach for estimating the potential aggregate health hazards

associated with the occurrence of chemical mixtures in environmental media." However, as noted, the health endpoints for the four PFAS included in the HI are different, with the exception that PFHxS and PFBS both have thyroid effects. Therefore, DEP questions whether it is appropriate to use the HI approach to regulate these four PFAS.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053349)

While EPA notes it received a favorable review for developing the mixtures assessment approaches,[FN65: U.S. EPA. Framework for Estimating Noncancer Health Risks Associated with Mixtures of Per- and Polyfluoroalkyl Substances (PFAS). 2023, EPA–822–P–23–003, at page 4, available at: https://www.epa.gov/system/files/documents/202303/PFAS%20Mix%20Framework%20Public%20Review%20Draft%2009%20March%202023.pdf.] it concedes that the favorable review was for approaches "that rely on a health protective assumption of dose additivity based on a common health outcome, instead of a common mode of action (MOA)." [FN66: Id.] In this proposed rule, however, EPA is not applying a framework that relies on a common health outcome or a common mode of action. For the four PFAS, EPA is mixing and matching distinct endpoints. As a critical effect, EPA is relying on the thyroid endpoint for PFHxS and PFBS, bodyweight changes for PFNA, and liver lesions for HFPO-DA.

This approach, which combines disparate endpoints, appears to be unprecedented in a regulatory action. In its report to EPA, the SAB stated: "In general, the screening level Hazard Index (HI) approach, in which Reference Values (RfVs) for the mixture components are used regardless of the effect on which the RfVs are based, is appropriate for initial screening of whether exposure to a mixture of PFAS poses a potential risk that should be further evaluated." [FN67: U.S. EPA. Transmittal of the Science Advisory Board Report titled, ''Review of EPA's Analyses to Support EPA's National Primary Drinking Water Rulemaking for PFAS.'' EPA–22–008, 202, at page 92, available at: https://sab.epa.gov/ords/sab/f?p=114:12:15255596377846.] The approach EPA proposes as an MCL, in the words of the SAB, is an approach for "initial screening." And if potential risks are seen, they should be "further evaluated."

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Ramboll US Consulting (Doc. #3072-55, SBC-046372)

Good afternoon. My name is Harvey Clewell, and I'm a principal consultant at Ramboll US Consulting. I've been conducting research on the pharmacokinetics mode of action of perfluoroalkyl substances for more than 20 years. I'm currently serving as a consultant of the American Water Works Association, but the opinions expressed today are my own. Over the last 30 years, I've assisted EPA on risk assessments for a variety of compounds, serving on the EPA's

fit for scientific advisory panel, EPA's scientific advisory board, and an external peer reviewer for EPA guidelines. I believe that the approaches used in the PFAS National Primary Drinking Water Regulation represent a return to the risk assessment process used in the 1970s and 80s when highly conservative default approaches were uniformly applied to all chemicals. However, in the 1990s under the leadership of William Farland, the EPA began the development of a new approach for conducting risk assessments that was based on a chemical's mode of action. In the current PFAS assessments, consideration of mode of action information to support the evaluation of studies and make qualitative decisions about the most appropriate risk assessment approach is completely inadequate. I was appalled to find that the EPA is proposing to use a hazard index approach for regulation of drinking water concentrations of four PFAS based on critical effects that are based on different endpoints and different target tissues. They attempt to defend this approach using supporting statements that are both inaccurate and contradictory. For example, they try to make an argument for a common mode of action that the diverse effects of various PFAS are all associated with a "common disruption of cellular signaling," while at the same time they indicate that it's necessary to use an approach based on common outcome rather than common mode of action due to the inadequate mode of action information on some PFAS. Inexplicably, the EPA then concludes that the inadequate mode of action data supports the hazard index approach that they use, which was based on different endpoints and different issues, not a common outcome. However, the use of hazard index based on a combination of endpoints for multiple target issues is not supported by any National Risk Assessment Agency except for the use in preliminary screening. The EPA risk assessment forum 2001 mixtures guidance states, "because the hazard index is tied to a specific effect, the underlying data should be on that effect. Substituting data on the critical effect introduces an unknown degree of conservatism so that the hazard index is inflated by an unknown amount."

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

American Water Works Association (AWWA) (Doc. #1759, SBC-045647)

2. Comments on the Hazard Index Approach

USEPA has proposed the use of a General HI approach for regulation of drinking water concentrations of four PFAS: PFNA, PFHxS, PFBS, and GenX (USEPA 2023g, p.8-18). However, rather than following the recommendation of the SAB (USEPA 2022a) to conduct the assessment on the basis of common outcome, the Hazard Index for these 4 compounds are calculated using critical effects (RfDs or MRLs) that are based on different endpoints and target tissues:

• PFNA: Delayed development in mouse offspring.

• PFHxS: Thyroid follicular epithelial hypertrophy/hyperplasia in parental male rats.

• PFBS: Decreased thyroxine in mouse offspring.

• GenX: Liver toxicity in female rat dams.

USEPA attempts to defend this approach using arguments that are inaccurate and contradictory. Initially, USEPA tries to make a broad claim that the diverse effects of PFAS are all associated with a common mechanism involving disruption of cellular signaling:

"PFAS, including HFPO-DA, PFBS, PFNA, and PFHxS, disrupt signaling of multiple biological pathways resulting in common adverse effects on several biological systems and functions, including thyroid hormone levels, lipid synthesis and metabolism, development, and immune and liver function (ATSDR 2021; EFSA 2018, 2020; USEPA 2022c)." (USEPA 2023g, p.2)

However, the USEPA suggestion that PFAS causes common disruption of biological pathway signaling that results in common adverse effects is essentially an argument for a common mode of action. This argument is difficult to support, given the agency's determination that information to support a common mode of action for PFAS is inadequate:

"Because PFAS are an emerging chemical class of note for toxicological evaluations and human health risk assessment, mode of action (MOA) data may be limited or not available for many PFAS." (USEPA 2023g, p.3).

Moreover, in contradiction to the USEPA suggestion of a common mode of action across all PFAS, the agency concluded in the USEPA Toxicity Assessment for GenX (USEPA 2021a), one of the 4 chemicals included in the HI, that the liver effects of GenX are not consistent with there being a common mode of action for all PFAS:

"Although there is evidence for a PPARα MOA in the liver, particularly in the highdose groups in the available studies, data indicate that liver toxicity extends beyond a single PPARα-based MOA." (USEPA 2021a, p.84).

USEPA then makes a case for an assumption of dose additivity based on common outcome rather than common mode of action (USEPA 2023g, p.3), citing the USEPA (2000) mixtures guidance. Inexplicably, the USEPA applied a General HI approach across different outcomes for each chemical, apparently based on their assertion of a common mode of action (above), and despite the fact that the multi-outcome approach clearly ignores the recommendation of the SAB (USEPA 2022a). It is also inconsistent with existing USEPA guidelines.

USEPA Mixtures Guidance (1986) does not support the use of dissimilar effects in a Hazard Index: "Since the assumption of dose addition is most properly applied to compounds that induce the same effect by similar modes of action, a separate hazard index should be generated for each end point of concern. Dose addition for dissimilar effects does not have strong scientific support, and, if done, should be justified on a case-by-case basis in terms of biological plausibility." (USEPA 1986, p.9)

The USEPA Risk Assessment Forum (2000) Mixtures Guidance clearly indicates that the use of critical effects from multiple tissues in a Hazard Index is generally inappropriate. The guidance describes the HI method only in terms of similarity in target organ:

"The Hazard Index method has weaker assumptions and data requirements, is more generally applicable, and has more uncertainty in the resulting assessment. Instead of requiring knowledge of similar mode of action, the Hazard Index method requires only similarity in target organ." (USEPA 2000, p.71)

"One of the key desirable features is the constraint to use only data on the effect of concern. Because the Hazard Index is tied to a specific effect, the underlying data should be on that effect. Substituting data on the critical effect introduces an unknown degree of conservatism, so that the Hazard Index is inflated by an unknown amount." (USEPA 2000, p.85)

"The use of an acceptable level in the relative toxicity scaling factor (e.g. 1/RfD) may be overly health protective in that the RfD (or RfC) is based on the critical effect, defined as the toxic effect occurring at the lowest dose. When the Hazard Index is calculated for some different, less sensitive effect, the RfD will be too low, so the factor (1/RfD) will overestimate the relative toxicity and the Hazard Index will be too large. One alternative that avoids this critical effect conservatism is to use a toxicity-based exposure level that is specific to the target organ of interest and is derived similarly to an RfD (or RfC). For oral exposures, this value is called the target organ toxicity dose or TTD (Mumtaz et al., 1997)." (USEPA 2000, p.82)

Indeed, the use of a Hazard Index based on the combination of endpoints from multiple target tissues, apart from screening purposes, is not supported by any national risk assessment agency.

It is inconsistent with ATSDR guidance.

The ATSDR (2022) Public Health Assessment Guidance Manual indicates that when "the health guideline for each contaminant is based on different target organs, health assessors will need to calculate a target-organ-specific HQ for each contaminant. These target-organ HQs can now be added together to give a Tier 3 HI based on the same target organ." (ATSDR 2022, p.8)

The ATSDR Framework for Assessing Health Impacts of Multiple Chemicals and Other Stressors (2018) indicates that the use of different target organ toxicities is reserved for screening:

"Because it is based on the assumption of dose additivity, the hazard index method is most appropriately applied to components that cause the same effect by the same mechanism or mode of action. In practice, it may be applied to components with different target organs as a screening measure." (ATSDR 2018, p.43)

USEPA (2023g) does not provide any justification for failing to apply the Target-organ Toxicity Dose (TTD) methodology that ATSDR has developed specifically to address situations where there is an overlap in effects across a mixture of chemicals, but where the critical effects are different: "A Target-organ Toxicity Dose (TTD) for each end point of concern is calculated using appropriate MRL (or RfD) methodology, and then used in estimating the end-point specific HQs and hazard indices." (ATSDR 2018, p.45)

Use of the ATSDR methodology is particularly important in the case of this NPDWR, since the General HI used by the agency is based on the critical (lowest) effect for each chemical, regardless of target tissue. As pointed out by ATSDR, a HI based on TTDs will certainly be higher than one based on the General HI, indicating that the currently proposed General HI approach is overly conservative.

The draft mixtures framework (USEPA 2021b) referred to the HI based on multiple target tissues as a "Screening-Level HI" to differentiate it from a Target Organ Specific Hazard Index (TOSHI), which they indicated would be more consistent with the USEPA (2000) mixtures guidelines. The SAB specifically supported the USEPA Framework's use of the TOSHI rather than the Screening Level HI:

"The SAB supports dose additivity based on a common outcome, instead of a common mode of action as a health protective default assumption and does not propose another default approach." (USEPA 2022a, p.90)

However, the SAB indicated that the agency should avoid referring to the multiple target tissue HI approach as a "Screening-Level HI", to avoid the appearance of disparaging the work of states that have been using it in their regulations:

"Methods analogous to those classified by USEPA as 'Screening Level' or 'Tier 1' in the framework are potentially being used by states in a decision-making capacity. Issuance of this framework without recognition of that fact may create confusion for public water supplies and risk communication challenges for the public." (USEPA 2022a, p.3-94)

In response to this SAB concern, the revised Framework (USEPA 2023h) refers to the Screening Level HI as a "General HI". USEPA then applied the General HI approach rather than the TOSHI approach in deriving the MCLG for mixtures of 4 PFAS (USEPA 2023g). However, as pointed out above, the USEPA SAB (2022a) had clearly indicated that the USEPA should base their assessment on common outcome, which would require the use of the TOSHI approach.

2.1 Conclusions and Recommendations

• The proposed use of a HI based on different target organs or endpoints for estimation of a regulatory value has no support in existing agency guidelines or those of other national and international authoritative bodies.

• The agency should delay promulgating a HI-based assessment until they have developed the necessary Target Tissue Doses (TTDs) to support the use of the TOSHI approach.

• The TTDs can readily be derived using the existing ATSDR methodology (ATSDR 2018).

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. In response to this comment, it is important to note a critical nuance to the Hazard Index variants, particularly in the context of application under SDWA. The general Hazard Index, selected for application to the four specified PFAS under this NPDWR, entails calculation of hazard quotients (HQs) using each chemical's RfD regardless of similarity in

critical effect. Application of the TOSHI (HI_{TO}) or a Hazard Index that uses Target Organ Toxicity-Dose (HI_{TTD}) would be less likely than the general Hazard Index to offer health protection against all potential effects.

Cleveland Water, City of Cleveland, Ohio (Doc. #1672, SBC-052955)

In table 42 of the preamble, EPA details the health outcomes associated with the PFAS compounds. EPA's reasoning for grouping these chemicals together was that they had additive health impacts. Cleveland Water seeks further clarification on this claim, and recommends EPA consider grouping these, and any future PFAS chemicals, based on similar health endpoints with the greatest support from data and science. The only row that has indication of potential health effects of all these four PFAS is birth weight, but two of the four chemicals have the subscript "5" and the chart indicates that, "evidence of the relationship between PFAS compound and the health outcome is not conclusive."

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Association of Metropolitan Water Agencies (AMWA) (Doc. #1738, SBC-053382)

AMWA seeks further evidence on EPA's claim that HI PFAS have additive adverse health effects and recommends EPA consider grouping these, and any future PFAS chemicals, based on similar health endpoints with the greatest support from data and science. EPA's reasoning for grouping these chemicals was that they had additive health impacts. In Table 42 of the preamble, EPA details the health outcomes associated with the HI PFAS compounds. The only row that indicates the potential health effects of all four PFAS is birth weight, but two of the four chemicals have the subscript "5" which signifies that "evidence of the relationship between PFAS compound and the health outcome is not conclusive."

EPA Response: Please see section 4.3.1 of the EPA response in this *Response to Comments* document.

4.3.2 Hazard Index Approach

Summary of Major Public Comments and EPA Responses

Many commenters supported the EPA's proposal to regulate mixtures of PFAS and agreed with the EPA's scientific conclusions about PFAS dose additivity and the agency's use of the Hazard Index approach to develop an MCLG for mixtures of PFHxS, PFNA, HFPO-DA, and/or PFBS. Many commenters opposed the EPA's conclusion about dose additivity and the use of the Hazard Index approach to regulate co-occurring PFAS. Some commenters disagreed with the use of toxicity reference values based on different adverse effects to derive the HBWCs for the four PFAS to develop the Hazard Index MCLG. A few commenters questioned the EPA's use of the general Hazard Index approach and suggested alternative approaches such as development of

individual MCLGs or a target organ-specific hazard index (TOSHI). Some commenters claimed that the EPA did not appropriately seek review from the Science Advisory Board (SAB), particularly on the application of the general Hazard Index as an approach to regulate PFAS mixtures under SDWA. The EPA response to these issues, as well as others expressed by individual commenters, are described in further detail below. For comments and the EPA responses on dose additivity and toxicological similarity, please see section 4.3.1 of the EPA response in this *Response to Comments* document.

Background on the use of the general Hazard Index approach to develop an MCLG for mixtures of four PFAS. The EPA's final determination that mixtures of the four PFAS "may have an adverse effect on the health of persons" is based on the health-protective conclusion that chemicals that are toxicologically similar (i.e., have similar observed adverse health effects, regardless of potency differences) following individual exposure should be assumed to act in a dose-additive manner when in a mixture unless data demonstrate otherwise (USEPA, 2024i; see discussion of dose additivity and toxicological similarity in section 4.3.1 of this *Response to Comments* document, and also sections II and IV.B of the preamble). The scientific record shows that these four PFAS—PFHxS, PFNA, HFPO-DA, and PFBS—are toxicologically similar (see USEPA (2024h) and section IV.B of the preamble). Therefore, these four PFAS are assumed to act in a dose-additive manner when present in a mixture. This means that where drinking water contains any combination of two or more of the four PFAS that are the subject of this action—PFHxS, PFNA, HFPO-DA, and PFBS—the hazard associated with each PFAS in the mixture must be added together to determine whether the mixture exceeds a level of public health concern.

The SDWA requires the agency to establish a health-based MCLG set at "a level at which no known or anticipated adverse effects on the health of persons occur and which allows for an adequate margin of safety." The MCLG "incorporates a margin of safety to reflect scientific uncertainty and, in some cases, the particular susceptibility of some groups (e.g., children) within the general population." S. Rep. No. 169, 104th Cong., 1st Sess. (1995) at 3. In the context of this NPDWR, the general Hazard Index is the approach used to determine if a mixture of two or more of four PFAS in drinking water—PFHxS, PFNA, HFPO-DA, and PFBS—exceeds the level of health concern with a margin of safety. A general Hazard Index equal to 1 is the MCLG for any mixture of those four PFAS.

Based on the scientific record, each of these four PFAS has an HBWC, which is set at the level below which adverse effects are not anticipated to occur and allows for an adequate margin of safety (see USEPA (2024h) and section IV.B. of the preamble). The general Hazard Index approach accounts for the measured drinking water concentration of each of the four PFAS in the mixture, and the toxicity (represented by the HBWC) of each of the four PFAS. The general Hazard Index is derived by first calculating the ratio of the measured concentration of each of the four PFAS to its toxicity (the HBWC) to yield a "HQ" for each of the four PFAS. HQs are then added together to account for the dose-additive health concerns that these PFAS present. Adding the four HQs together yields the general Hazard Index. If the general Hazard Index exceeds 1,

then the hazard from the combined amounts of the four PFAS present together in drinking water exceeds a level of public health concern.

The EPA has determined that in the context of SDWA, the general Hazard Index is an appropriate methodology for determining the level at and below which there are no known or anticipated adverse human health effects with an adequate margin of safety with respect to certain PFAS mixtures in drinking water. The general Hazard Index approach is the most practical approach for establishing an MCLG for PFAS mixtures that meets the statutory requirements outlined in Section 1412(b)(1)(A) of SDWA. As noted above, the general Hazard Index assesses the exposure level of each component PFAS relative to its HBWC, which is based on the most sensitive known adverse health effect (based on the weight of evidence) and considers sensitive population(s) and life stage(s) as well as potential exposure sources beyond drinking water. The general Hazard Index also accounts for dose-additive health concerns by summing the hazard contributions from each mixture component. In this way, the general Hazard Index approach ensures that mixtures of two or more of these four PFAS are not exceeding the level below which there are no known or anticipated adverse health effects and allows for an adequate margin of safety.

Some commenters expressed support for the EPA's proposed general Hazard Index approach to regulating mixtures of two or more of the four PFAS in drinking water. The commenters also stated that occurrence and co-occurrence of these four PFAS in public water systems (PWSs), as well as individual and dose-additive effects of these PFAS, justify the general Hazard Index approach. The EPA agrees that the general Hazard Index approach is the most scientifically sound and health-protective approach to deriving a PFAS mixtures MCLG which considers both their dose-additive health concerns and co-occurrence in drinking water.

Consideration of the different mixture assessment approaches, and selection of the general Hazard Index approach. In selecting an approach to develop the MCLG for mixtures of two or more of four PFAS—PFHxS, PFNA, HFPO-DA, and PFBS—the EPA followed its *Guidelines for the Health Risk Assessment of Chemical Mixtures* (USEPA, 1986), *Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures* (USEPA, 2000b, and *Risk Assessment Guidance for Superfund* (e.g., USEPA, 1991c). As described below and in USEPA (2024h), the EPA first considered whether data were available for the whole mixture or a "sufficiently similar" mixture, per agency guidance (USEPA, 1986; 2000b), and then considered several mixture component-based assessment methods (USEPA, 2024i), ultimately selecting the general Hazard Index approach for PFAS mixture MCLG derivation (USEPA, 2024h).

The EPA's guidance documents (USEPA, 1986; USEPA, 1991c; USEPA, 2000b) propose a hierarchy of mixtures assessment approaches, with the preferred approach being evaluation of health risk using hazard and dose-response data for a specific whole mixture of concern, or alternatively, a "sufficiently similar" mixture. Whole-mixture data are rare; there are often many chemical combinations and proportions in the environment (e.g., parent chemicals, metabolites, and/or abiotic degradants), introducing a level of complexity that complicates evaluation and characterization. The exponential diversity of PFAS co-occurring in different component

combinations and proportions makes whole-mixture evaluations complex and unfeasible. Due to differing fate and transport properties, biotic (metabolism) and abiotic (degradation) processes, pH, ultraviolet radiation, media temperature, and so on, chemicals commonly co-occur in the environment in an array of parent species, metabolites, and/or degradants, making characterization and evaluation of any given mixture complicated. In controlled experimental study designs, whole mixtures can be assembled with defined component membership and proportions, but the relevance of toxicity associated with exposure to a defined mixture in a laboratory setting may not be translatable to environmental mixtures of different component combinations and proportions across time and space in environmental media. The complexities associated with the diversity of PFAS co-occurring in different component proportions (see USEPA, 2024j) make evaluating each unique whole mixture of PFAS intractable. This is why component-based mixture assessment approaches are considered particularly useful and appropriate for addressing human exposure(s) to mixtures of PFAS (see Sections 5–7 in USEPA (2024i)). For a more detailed discussion on whole-mixture and component-based approaches for PFAS risk assessment, please see the final *PFAS Mixtures Framework* (USEPA, 2024i).

The EPA considered several component-based assessment approaches to develop an MCLG for mixtures of PFHxS, PFNA, HFPO-DA, and/or PFBS under an assumption of dose additivity. The approaches are described in detail in the EPA's *Framework for Estimating Noncancer Health Risks Associated with Mixtures of PFAS* ("PFAS Mixtures Framework," USEPA, 2024i) and include the general Hazard Index , the target organ-specific Hazard Index (TOSHI), the Relative Potency Factor (RPF) approach, and the mixture-BMD approach. As part of the technical support materials for the PFAS NPDWR, the EPA's draft PFAS Mixtures Framework (USEPA, 2021g) was submitted to the SAB for expert review. The SAB supported the EPA's proposed component-based approaches under the assumption of dose additivity in the absence of information to support a conclusion other than dose additivity (please see section 4.3.1 of the EPA response in this *Response to Comments* document). Following the SAB review, the EPA addressed the SAB's recommendations. Then, the EPA solicited public comment on the draft PFAS Mixtures Framework as part of the proposed NPDWR (88 FR 18638; USEPA, 2023e). The EPA evaluated potential component-based mixture assessment options, and ultimately proposed using the general Hazard Index approach as the most appropriate option based on available data and consistent with the statutory definition of MCLG.

Some commenters suggested that the EPA has not followed its guidance (USEPA, 2000b), specifically that the agency did not use a "sufficiently similar mixture" where "components and respective portions exist in approximately the same pattern," and suggested that there has to be consistent co-occurrence of the mixture components. The EPA disagrees with these comments. As described above, although use of data from whole mixtures or "sufficiently similar mixtures" is ideal in a theoretical sense, it is not practical, possible, or necessary for evaluating mixtures of PFAS in drinking water. Instead, the EPA is using the general Hazard Index approach, a longstanding component-based mixtures assessment approach which was endorsed by the SAB in the context of assessing risk associated with exposure to PFAS mixtures in drinking water (USEPA, 2022b), as discussed below. The goal of this component-based mixtures assessment

approach is to approximate what the whole-mixture toxicity would be if the whole mixture could be tested and relies on toxicity information for each individual component in a mixture (USEPA, 2000b). A whole-mixture approach for regulating mixtures of these four PFAS in drinking water is not possible because it would entail developing a single toxicity reference value (e.g., RfD) for one specific mixture of PFHxS, PFNA, HFPO-DA, and PFBS with defined proportions of each PFAS. Toxicity studies are typically conducted with only one test substance to isolate that particular substance's effects on test organisms, and whole-mixture data are exceedingly rare. There are no known whole-mixture studies for PFHxS, PFNA, HFPO-DA, and PFBS, and even if they were available, a toxicity reference value derived from such a study (i.e., a single RfD for a specific mixture of these four PFAS) would only be directly applicable to that specific mixture. Thus, a more flexible approach is necessary—one that considers the potential for the four PFAS to co-occur in different combinations and at different concentrations across time and space. The general Hazard Index approach affords this flexibility; the general Hazard Index indicates risk from exposure to a mixture and is useful to ensure a health-protective MCLG for PFAS mixtures that can be spatially and/or temporally variable. Given the variability of PFAS occurrence in drinking water across the nation (USEPA, 2024j), the general Hazard Index allows the EPA to regulate mixtures of these PFAS in drinking water by taking into account site-specific data at each PWS. HQs for the four different PFAS are expected to differ depending on the actual measured concentrations of each of the four PFAS at each PWS. The general Hazard Index approach thus allows for flexibility beyond a one-size-fits-all approach and is tailored to address risk at each PWS. Furthermore, the EPA's application of the general Hazard Index approach accounts for the dose additivity that was the basis for the EPA's final determination to regulate mixtures of two or more of these PFAS.

The general Hazard Index approach and the TOSHI. Some commenters opposed the EPA's use of a general Hazard Index as opposed to a target organ-specific Hazard Index (TOSHI) and suggested the use of a TOSHI instead. The EPA disagrees with these comments. The use of the general Hazard Index approach to develop an MCLG for mixtures of PFHxS, PFNA, HFPO-DA, and/or PFBS is scientifically sound, supported by external peer review (SAB), consistent with EPA guidance and guidelines (USEPA, 1986; USEPA, 1991c; USEPA, 2000b), and allows for the determination of an MCLG that is consistent with the statutory definition of an MCLG. Specific reasons why the general Hazard Index represents the more health-protective approach over the TOSHI are described below. A few commenters mentioned the RPF approach and agreed with the EPA that the general Hazard Index approach is preferred in this situation. The EPA did not receive comments on the mixture-BMD approach.

The EPA considered the two main types of Hazard Index approaches: 1) the general Hazard Index , which allows for component chemicals in the mixture to have different health effects or endpoints as the basis for their toxicity reference values (e.g., RfDs, minimal risk levels), and 2) the TOSHI, which relies on toxicity reference values based on the same specific target organ or system effects (e.g., effects on the liver or thyroid; effects on developmental or reproductive systems) (USEPA, 2000b). The general Hazard Index approach uses the most health-protective RfD (or minimal risk level) available for each mixture component, irrespective of whether the

RfDs for all mixture components are based on effects in the same target organs or systems. These "overall" RfDs (as they are sometimes called) are protective of all other adverse health effects because they are based on the most sensitive known endpoints as supported by the weight of the evidence. As a result, this approach is protective of all types of toxicity/adverse effects, and thus ensures that the MCLG is the level at and below which there are no known or anticipated adverse human health effects with an adequate margin of safety with respect to certain PFAS mixtures in drinking water.

The TOSHI produces a less health protective indicator of risk than the general Hazard Index because the basis for the mixture component toxicity reference values has been limited to a specific target organ or system effect, which may occur at higher exposure levels than other effects (i.e., be a less sensitive endpoint). In other words, a TOSHI may not be health protective compared to the general Hazard Index if available data for a mixture component show effects in other organs at lower exposure levels compared to the critical effect observed in the target organ used for the TOSHI. Additionally, since a TOSHI relies on toxicity reference values aggregated for the same specific target organ or system endpoint/effect, an absence or lack of data on the specific target organ or system endpoint/effect for a mixture component may result in that component not being adequately accounted for in this approach (thus, underestimating health risk of the mixture). A TOSHI can only be derived for those PFAS for which the same target organ or system endpoint/effect-specific RfDs have been calculated. For example, a TOSHI based on changes in thyroid effects illustrates why the target organ-specific approach underestimates risk in the context of these four PFAS in drinking water. To develop a thyroid effects-based TOSHI for mixtures of these four PFAS, only those PFAS with chronic toxicity reference values based on thyroid effects -- PFHxS (minimal risk level) and PFBS (RfD) – would be included in the TOSHI calculation; HFPO-DA and PFNA have chronic toxicity reference values based on other effects (i.e., liver and developmental effects, respectively) and thus would not be included in a thyroid effects-based TOSHI. Although thyroid effects are not the basis for the RfDs for HFPO-DA and PFNA, studies have shown that these two PFAS significantly affect the thyroid; for example, both have been shown to significantly affect serum thyroid hormone levels (reduced T4, T3) (Conley et al., 2019; NTP, 2019; please see section 4.3.1 of the EPA response in this *Response to Comments* document). According to the Interagency Report to Congress on PFAS, "Multiple studies on diverse species (developing rodents and fish) suggest that some PFAS (e.g., PFOS, PFOA, *PFNA, GenX chemicals*, PFHxS, PFDA, PFBA, PFBS, PFHxA) interfere with thyroid hormone signaling pathways and thyroid homeostasis through various mechanisms, including regulation of hepatic glucuronidation enzymes and deiodinases in the thyroid gland" (emphasis added, United States OSTP, 2023). Therefore, a thyroid-specific Hazard Index that excluded HFPO-DA and PFNA would underestimate the dose additivity concerns for thyroid effects from the total mixture.

The EPA's chemical mixtures guidance supports use of the general Hazard Index.
Many PFAS have data gaps in epidemiological or animal toxicological dose-response information for multiple types of health effects, thus limiting derivation of target organ-specific toxicity reference values; target organ-specific toxicity reference values for the same target for

all four PFAS are not currently available for PFHxS, PFNA, HFPO-DA, and PFBS. The EPA's *Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures* recognizes the potential for organ- or system-specific data gaps and supports use of overall RfDs in a general Hazard Index approach, stating, "The target organ toxicity dose (TTD) is not a commonly evaluated measure and currently there is no official EPA activity deriving these values, as there is for the RfD and RfC" … "Because of their much wider availability than TTDs, standardized development process including peer review, and official stature, the RfD and RfC are recommended for use in the default procedure for the HI" (USEPA, 2000b). Even if target organ-specific toxicity reference values (TTDs) were available for PFHxS, PFNA, HFPO-DA, and PFBS, the general Hazard Index approach would still be more appropriate for this specific application because it is protective of all adverse health effects rather than just those associated with a specific organ or system, consistent with the statutory definition of MCLG.

The EPA's risk assessment guidance for CERCLA assessments identifies the general Hazard Index approach as a health-protective and simplistic way to assess mixture risk: "Segregation of hazard indices requires identification of the major effects of each chemical including those seen at higher doses than the critical effect (e.g., the chemical may cause liver damage at a dose of 100 mg/kg-day and neurotoxicity at a dose of 250 mg/kg-day). Major effect categories include neurotoxicity, developmental toxicity, reproductive toxicity, immunotoxicity, and adverse effects by target organ (i.e., hepatic, renal, respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, and dermal/ocular effects). *Although higher exposure levels may be required to produce adverse health effects other than the critical effect, the RfD can be used as the toxicity value for each effect category as a conservative and simplifying step*" (italics added for emphasis; pg. 8-15 from USEPA (1991c)).

The SAB supported the general Hazard Index approach. The EPA directly asked the SAB about the utility and scientific defensibility of the general Hazard Index approach (in addition to other methods, including TOSHI) during the 2021–2022 review of the EPA's draft *Framework for Estimating Noncancer Health Risks Associated with Mixtures of PFAS*. Specifically, the EPA asked the SAB to "Please provide specific feedback on whether the HI approach is a reasonable methodology for indicating potential risk associated with mixtures of PFAS. If not, please provide an alternative;" and "Please provide specific feedback on whether the proposed HI methodologies in the framework are scientifically supported for PFAS mixture risk assessment" (USEPA, 2022b). In its report (USEPA, 2022b), the SAB stated its support for the general Hazard Index approach:

"In general, the screening level Hazard Index (HI) approach, in which Reference Values (RfVs) for the mixture components are used regardless of the effect on which the RfVs are based, is appropriate for initial screening of whether exposure to a mixture of PFAS poses a potential risk that should be further evaluated. Toxicological studies to inform human health risk assessment are lacking for most members of the large class of PFAS, and mixtures of PFAS that commonly occur in environmental media, overall. For these reasons, the HI methodology is a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of

chemical mixtures in environmental media. The HI is an approach based on dose dose additivity that has been validated and used by the EPA. The HI does not provide quantitative risk estimates (i.e., probabilities) for mixtures, nor does it provide an estimate of the magnitude of a specific toxicity. This approach is mathematically straightforward and may readily identify mixtures of potential toxicological concern, as well as identify chemicals that drive the toxicity within a given mixture."

The EPA's use of the general Hazard Index under SDWA is well supported and not inconsistent with past application in other contexts. A few commenters stated that it is inappropriate to use the general Hazard Index in the context of a drinking water rule because it is a screening tool. In fact, the EPA initially proposed a tiered approach in its draft PFAS Mixtures Framework (USEPA, 2021g), whereby the general Hazard Index and TOSHI were considered Tier 1 (for screening purposes) and the more refined/data-intensive approaches (RPF and mixture-BMD) were proposed as Tier 2. During its 2021–2022 review of the draft PFAS Mixtures Framework, the SAB was critical of this proposed tiered approach for PFAS due to the paucity of data for these emerging chemicals and urged the EPA to restructure the PFAS Mixtures Framework to eliminate tiering/screening approach. One of the highlighted consensus recommendations from the SAB during its review of the draft PFAS Mixtures Framework was:

The "EPA should consider using a menu-based framework to support selection of fit-for-purpose approaches, rather than a tiered approach as described in the draft Mixtures document. Tiered approaches that require increasingly complex information before reaching a final decision point can be extremely challenging for data-poor chemicals such as PFAS" (USEPA, 2022b).

The SAB recognized the need for regulatory agencies to make decisions in the face of uncertainty to reduce exposures to PFAS. The SAB stated,

"Given the agency's desire to support fit-for-purpose approaches, not every PFAS mixture scenario will be one that warrants a tiered or hierarchical approach. In some instances, *an HI or target-organ-specific hazard indices (TOSHI) might provide enough information for decision-making about PFAS (or other chemicals) contamination in drinking water* (or other media). *Tiered approaches that require increasingly complex information before reaching a final decision point can be extremely challenging for data-poor chemicals such as PFAS. Data gaps identified in a such tiered methodologies could result in a bottleneck through which these chemicals may never emerge*…" (italics added for emphasis; USEPA, 2022b).

Further, the SAB did not say that the Hazard Index use was limited to screening, nor that the agency would or should be prohibited from considering its use in any regulatory or nonregulatory application. Indeed, the SAB concluded that:

"The HI methodology is a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media. The HI is an approach based on dose additivity (DA) that has been validated and used by the EPA…. This approach is mathematically straightforward and may readily identify mixtures of potential

toxicological concern, as well as identify chemicals that drive the toxicity within a given mixture" (USEPA, 2022b).

In response to SAB comments that were critical of the tiered/screening approach, the EPA restructured the PFAS Mixtures Framework as a data-driven, flexible approach to facilitate PFAS mixtures assessment in various decision contexts (see Section 4.2 and Figure 4-1 in USEPA, 2024i). In the final PFAS Mixtures Framework, the EPA included a discussion of key steps in the framework, including problem formulation and scoping, assembling information, evaluating data objectives, considering the data landscape to select component-based mixture assessment approach(es), and implementing component-based mixture assessment approach(es) (see Section 4.2 in USEPA, 2024i).

The general Hazard Index is a well-established methodology that has been used for several decades in at least one other regulatory context to account for dose additivity in mixtures assessments. The EPA routinely uses the Hazard Index approach to consider the risks from multiple contaminants of concern in the Remedial Investigations and Feasibility Studies for cleanup sites on the Superfund National Priorities List under CERCLA. Noncarcinogenic effects are summed to provide a Hazard Index that is compared to an acceptable index, generally 1. This approach assumes dose additivity in the absence of information on a specific mixture. These assessments of hazards from multiple chemical exposures are important factors to help inform the selection of remedies that are ultimately captured in the Superfund Records of Decision.

The use of the general Hazard Index MCLG as a risk indicator is consistent with SDWA. Some commenters claimed that the general Hazard Index was not appropriate for use in this SDWA context because it is an indication of appreciable risk, rather than an estimate of the concentration of the mixture in water that may result in adverse health outcomes after a specific period of exposure. On the contrary, under the SDWA, the MCLG is set at the level *at and below which* there are no known or anticipated adverse human health effects with an adequate margin of safety. Setting an MCLG at a level that may result in adverse health outcomes after exposure would be inconsistent with this statutory definition.

Relevance of guidance from other programs/agencies/panels. A few commenters stated that that the general Hazard Index approach is not consistent with mixtures guidance developed by other programs/agencies and under other statutes, including the EPA's *Draft Proposed Principles of Cumulative Risk Assessment under the Toxic Substances Control Act (TSCA)* (USEPA, 2023l) and ATSDR's *Framework for Assessing Health Impacts of Multiple Chemicals and Other Stressors* (ATSDR, 2018). The TSCA cumulative risk guidance defines cumulative risk assessment in general (i.e., not specifically for PFAS mixtures) within the requirements of TSCA. In addition, the Hazard Index MCLG for PFAS mixtures and the PFAS Mixtures Framework are not "cumulative risk assessment." Cumulative risk assessment is much broader in terms of the integration across multiple exposure routes/scenarios, and often includes stressors other than chemicals (e.g., physical conditions; microbial risks; nutritional status; socioeconomic factors; etc.) (see further discussion in the EPA's PFAS Mixtures Framework, USEPA, 2024i).

Regarding the ATSDR Framework, that document is a general framework and not specific to PFAS. Additionally, the ATSDR approach is a tiered approach similar to what the EPA originally proposed in its draft PFAS Mixtures Framework (USEPA, 2021g), which was criticized by SAB in the context of PFAS in drinking water (see above).

A few commenters claimed that the EPA's approach was inconsistent with the conclusions of a recent panel of independent experts (Anderson et al., 2022). Commenters mischaracterized the panel's findings by stating that "grouping PFAS together without data supporting common mode of action and potency is inappropriate." The full quote from Anderson et al. (2022) is as follows: "Ideally, PFAS groupings should be based only on common toxic MOAs **and/or target organs. Only those PFAS that affect the same target organ/tissue/system should be grouped** and assessed for dose additive or response additive approaches. Unfortunately, these data are the least likely to be available for the majority of PFAS. Added complexity noted is that individual PFAS are likely to have different MOA/AOP across tissues/organs" (emphasis added). As stated in section 4.3.1 of the EPA response in this *Response to Comments* document, the EPA's mixture assessment approach is based on similar adverse effects due to the absence of MOA data, an approach that was supported by the SAB in its review of the PFAS Mixtures Framework in the context of development of the PFAS NPDWR. The Anderson et al. (2022) panel agrees that grouping PFAS that affect the "same target organ/tissue/system" is supportable (see Fig. 1 in Anderson et al., 2022). These four PFAS affect many of the same target organs/tissues/systems (please see section 4.3.1 of the EPA response in this *Response to Comments* document).

The EPA appropriately sought comments from the SAB. The EPA disagrees with commenters that the agency did not seek adequate consultation from the SAB in the development of the MCLG and NPDWR. SDWA Section 1412(e) requires that the EPA "request comments" from the SAB "prior to proposal" of the MCLG and NPDWR. Consistent with this statutory provision, the EPA began its engagement with the SAB on December 12th, 2021, seeking guidance on several charge questions related to identifying and quantifying the health effects associated with PFOA and PFOS exposure; dose additivity and methods to assess mixtures of PFAS; and the agency's proposed methodology to determine avoided cases of CVD events. The proposed rule was signed on March 14, 2023. As discussed in the proposed rule, the SAB PFAS Review Panel met virtually via a video meeting platform on December 16, 2021, and then had three (3) subsequent meetings on January 4, 6, and 7, 2022 to deliberate on the agency's charge questions, which included a question specifically focused on the utility and scientific defensibility of the general Hazard Index approach in the context of mixtures risk assessment in drinking water. Another virtual meeting was held on May 3, 2022 to discuss the SAB PFAS Review Panel's draft report. Oral and written public comments were considered throughout the advisory process. The SAB provided numerous recommendations to the EPA which can be found in the SAB's final report (USEPA, 2022b). The EPA addressed the SAB's recommendations and described the EPA response to SAB recommendations in its *EPA Response to Final Science Advisory Board Recommendations (August 2022) on Four Draft Support Documents for the EPA's Proposed PFAS National Primary Drinking Water Regulation* (USEPA, 2023d) and also in this *Response to Comments* document which responds to public comments on the proposed

PFAS NPDWR (USEPA, 2023). Further discussion on the EPA consultations and stakeholder engagement activities can be found in section XIII of the preamble.

The agency also disagrees with commenters who contend that the EPA must seek advice from the SAB on all aspects of the MCLG and NPDWR. The statute does not dictate on which scientific issues the EPA must request comment from the SAB but instead states only that the agency must do so before proposal of an MCLG and NPDWR. The EPA disagrees with commenters who suggested that the EPA must go back to the SAB on issues prior to proposal or throughout the rulemaking process. As part of the development of a drinking water rule, the EPA typically considers and evaluates hundreds of scientific issues. SDWA reasonably provides the EPA with the discretion to use its technical expertise to choose which to send to the SAB for comment prior to the proposal. To read the SDWA's SAB comments requirement as broadly as some commenters urge would render compliance with SDWA's two-year proposed rule deadline an impossibility, as it would, among other things, require EPA to complete its complex scientific work before consulting with the SAB and to engage in a never-ending cycle of consultation.

In meeting the statutory mandate to request comment from the SAB, the EPA requests comment on the scientific questions that are the most critical to the EPA's derivation of the proposed MCLG and NPDWR. While the key questions vary with the contaminant at issue and timing of SAB review, they are often focused on issues or products on which there has not been extensive prior peer review and/or that employ novel approaches.[2] In this case, the EPA sought comments on four documents before proposal: *Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) in Drinking Water* (USEPA, 2021b); *Proposed Approaches to the Derivation of a Draft Maximum Contaminant Level Goal for Perfluorooctanesulfonic Acid (PFOS) in Drinking Water* (USEPA, 2021c); *Analysis of Cardiovascular Disease Risk Reduction as a Result of Reduced PFOA and PFOS Exposure in Drinking Water* (USEPA, 2021l); and *Draft Framework for Estimating Noncancer Health Risks Associated with Mixtures of PFAS* (USEPA, 2021g). The first three focus on the MCLGs and NPDWRs for PFOA and PFOS, while as discussed elsewhere, the last was critical to the EPA's ability to derive an MCLG and NPDWR for a PFAS mixture. These two areas represent where the proposed PFAS MCLGs and NPDWRs posed critical issues that had not yet been subject to peer review where SAB commentary would be most valuable. In contrast, the ATSDR *Toxicological Profile for Perfluoroalkyls*, which covers 10 PFAS including PFHxS and PFNA, as well as the EPA toxicity assessments for PFBS and HFPO-DA had been externally peer reviewed prior to the SAB review of the EPA's four documents.

[2] For more information on the subsets of issues addressed in EPA's prior requests for comment from the SAB, see, e.g. Arsenic Rule Benefits Analysis: an SAB Review, https://nepis.epa.gov/Exe/ZyPDF.cgi?Dockey=P1004JZG.txt (focusing SAB review on benefits of regulation, health endpoints, and uncertainties), and Perchlorate - Approaches for Deriving Maximum Contaminant Level Goals for Drinking Water, https://sab.epa.gov/ords/sab/r/sab_apex/sab/advisoryactivitydetail?p18_id=2221&clear=18&session=7288224619303 (SAB review focused on adverse effects during various life stages, approaches for deriving and MCLG, and strengths and limitations of available biomonitoring and epidemiological studies).

The four Hazard Index PFAS have the same or similar effects but with different potencies. Although these four PFAS elicit many of the same or similar adverse health effects, the most sensitive known endpoint for each of the four PFAS is different, and thus the toxicity reference values used to calculate the HBWCs in the general Hazard Index approach are different. Epidemiological and/or experimental animal studies have demonstrated that exposure to PFHxS, PFNA, HFPO-DA, and PFBS individually is associated with many of the same observed adverse health effects (e.g., effects on lipids, as well as developmental, immune, endocrine, and hematologic endpoints; please see section 4.3.1 of the EPA response in this *Response to Comments* document), but with differing potencies for effect(s). In other words, two or more PFAS may elicit the same or similar adverse effects, but at different exposure levels; for example, liver effects are associated with all four PFAS (PFHxS, PFNA, HFPO-DA, and PFBS; please see section 4.3.1 of the EPA response in this *Response to Comments* document) but HFPO-DA is the only one of the four for which liver effects represent the most sensitive known endpoint and serve as the basis for its toxicity reference value (i.e., RfD). The fact that the toxicity reference values (i.e., RfDs or minimal risk levels) for the four PFAS are based on different health endpoints does not mean that the four PFAS are not toxicologically similar; rather, it means that based on the available data, the most sensitive endpoint currently known is different for each of these PFAS. The general Hazard Index approach uses the most health-protective toxicity reference value available for each of the four PFAS to derive HBWCs, irrespective of whether they are based on effects in the same target organs or systems. Since each RfD (or minimal risk level) is based on the most sensitive known endpoint based on the weight of evidence (i.e., toxicity reference value selection is not limited to a specific organ or system), this approach is protective of all other adverse health effects. This approach of allowing for component chemicals in the mixture to have different health effects or endpoints as the basis for their toxicity reference values is consistent with EPA guidance (see examples in USEPA, 1991c; USEPA, 2000b) and was supported by SAB (see below).

A few commenters suggested that because the toxicity reference values for the four PFAS in the general Hazard Index approach are based on different endpoints, the approach is inconsistent with EPA guidance which indicates that the premise of the Hazard Index is dose additivity where the mixture components have similar toxic effects on the same organ or biological system. The EPA disagrees that the EPA's approach is inconsistent with its guidance. As described above and in the EPA Essay Response 4.3.1, these four PFAS do elicit the same or similar adverse health effects on many of the same organs and/or systems. The toxicity reference values for the four PFAS are not all based on the same endpoint because the most sensitive known endpoint is different for each of them. This does not mean that the four PFAS do not share many of the same or similar adverse health effects. Two things are true at the same time: 1) these four PFAS elicit many of the same effects in many of the same organs and systems; 2) the toxicity reference values are based on different effects because although the four PFAS affect many of the same endpoints, they do so at different exposure levels. Please see section 4.3.3 of the EPA response in this *Response to Comments* document for further discussion on HBWCs.

"Grouping" PFAS. Many commenters supported the EPA's interpretation of regulating a mixture as a "contaminant" that consists of a combination of certain PFAS, citing the EPA's broad authority under SDWA to set regulatory standards for groups of related contaminants and the EPA precedent for doing so under other NPDWRs including disinfection byproducts (DBPs; for total trihalomethanes [TTHMs] and the sum of five haloacetic acids [HAA5], (USEPA, 1979; 2006c)), as well as radionuclides (USEPA, 2000c) and polychlorinated biphenyls (PCBs). The EPA also noted some of these examples within the proposed rule. One commenter disagreed that these previous EPA grouping approaches are applicable to mixtures of the four PFAS, noting that TTHMs and HAA5 are byproducts of the disinfection process and are the result of naturally occurring compounds reacting with the disinfectants used in drinking water treatment; thus, their formation cannot be controlled and is dependent on the presence and amount of disinfectant. As a result of these factors, measuring them as a class is required; however, the four PFAS are not byproducts, and the presence of one PFAS does not change the presence of the other PFAS. Moreover, the commenter provided that related to radionuclides, alpha particles are identical regardless of their origination and using this example for PFAS is not supported since the four PFAS are fundamentally different. The EPA disagrees with this commenter. The SDWA definition of contaminant is very broad ("any physical, chemical or biological or radiological substance or matter" (emphasis added)) with no limitations, specific description, or requirement for how it is formed. The statute therefore easily encompasses a mixture, comprised of a combination of PFAS (chemical substances), as itself qualifying as a "contaminant" under SDWA. Moreover, to the extent the mixture is considered a "group," Congress clearly anticipated that the EPA would regulate contaminants by group (see section III.A.2 of the preamble). As a result, even if the PFAS "group" is different than other SDWA regulatory groupings, such a regulation is clearly authorized under the statute. Furthermore, it makes sense to treat these mixtures as a "contaminant" because the four PFAS share similar characteristics: it is substantially likely that they co-occur; the same treatment technologies can be used for their removal; they are measured simultaneously using the same analytical methods; they have shared adverse health effects; and they have similar physical and chemical properties resulting in their environmental persistence. Please see section III.A.2 of the final rule preamble and section 3.2 of the EPA response in this *Response to Comments* document for further information regarding the EPA's authority to regulate mixtures.

Form of MCLG/MCL. A couple of commenters suggested that the EPA set the PFAS mixture MCLG at a set concentration (e.g., 20 ppt). Setting one concentration nationally for all four PFAS combined would not account for the different potencies of the mixture components nor the spatial and temporal variability of PFAS concentrations in drinking water nationwide (USEPA, 2024j). As noted above, each PFAS within the mixture has an HBWC, which is set at the level below which adverse effects are not likely to occur and allows for an adequate a margin of safety. As described in USEPA (2024h), the HBWCs for PFNA, HFPO-DA, and PFHxS are each 10 ppt and the HBWC for PFBS is 2000 ppt. As indicated above, the general Hazard Index approach can be used to assess site-specific risk associated with variable mixtures of these four PFAS at individual PWSs.

The EPA disagrees with commenter assertions that the general Hazard Index approach is inconsistent with the SDWA and that the agency did not set a "maximum permissible level" and that it "is not actually a fixed standard." The statute does not require that the MCLG or MCL be a "fixed" level or standard. In any event, the MCLG and MCL are not variable: both are set at one (1). The exposure concentration (i.e., numerator in HQ) for each the four PFAS in the Hazard Index will vary over space and time, which is one reason the EPA is finalizing this approach to account for dose-additive health concerns. This approach is analogous to other NPDWRs regulated by an MCL where concentrations at sample locations can vary. Further, the underlying calculation is not mathematically different (i.e., summing up numbers and dividing) than a running annual average calculation which is used for determining compliance with many other contaminants, including synthetic organic contaminant (SOCs), volatile organic compounds (VOCs), most inorganic chemicals (IOCs), and disinfection byproducts. Based on occurrence data (USEPA, 2024j), the EPA expects that different PFAS mixtures at different PWSs will have different risk drivers (i.e., individual PFAS with the highest HQs) and so a one-size-fits-all approach with a set concentration for the total mixture of four PFAS is not appropriate. As stated above, this type of approach, i.e., setting one concentration nationally for all four PFAS combined, would not account for the different potencies of the mixture components or the spatial and temporal variability of PFAS concentrations in drinking water nationwide (USEPA, 2024j), and thus would be over-protective in some areas and under-protective in others.

Additionally, Section 1401(6) of SDWA defines the term ''contaminant'' to mean ''any physical, chemical or biological or radiological substance or matter in water.'' A mixture of two or more ''contaminants'' qualifies as a ''contaminant'' because the mixture itself is ''any physical, chemical or biological or radiological substance or matter in water.'' Section 1401(3) of SDWA defines the term "maximum contaminant level" to mean "the maximum permissible level of a *contaminant* in water which is delivered to any user of a public water system" (emphasis added). Therefore, in the general Hazard Index approach, mixtures of two or more of PFHxS, PFNA, HFPO-DA and PFBS constitute as a contaminant, and an MCL with Hazard Index value of 1 sets the maximum permissible level of that contaminant.

The agency also disagrees with some commenters' claims that dividing an exposure metric over a health metric (i.e., HQs in the general Hazard Index) is complex or difficult to understand. This calculation is similar to that used to determine the running annual average calculation (addition followed by division), which is used frequently for compliance calculations for other NPDWRs, including SOC's, VOCs, most IOCs, and disinfection byproducts. Regardless, to assist in the calculation of Hazard Index, the agency is developing a calculator tool for users. After finalization of the PFAS NPDWR, the EPA also intends to provide support to utilities, primacy agencies, and other interested parties to ensure successful rule implementation. For discussion on feasibility considerations for the Hazard Index MCLG, please see section 5.2.1 of the EPA response in this *Response to Comments* document. For additional discussion on the EPA's regulatory determination for mixtures of PFAS, please see section 3.2 of the EPA response in this *Response to Comments* document. For additional discussion on the Hazard Index MCL, please see section 5 of the EPA response in this *Response to Comments* document. For additional

discussion about the form of an MCLG/MCL, please see section 5.2.1 of the EPA response in this *Response to Comments* document.

Establishment of individual MCLGs for PFHxS, HFPO-DA, PFNA, and/or PFBS.
The EPA has determined that sufficient information is available to satisfy the statutory requirements for individual regulation of PFHxS, HFPO-DA, and PFNA (in addition to PFOA and PFOS). To support this determination, the EPA carefully examined the health effects information from available peer-reviewed final human health assessments as well as published studies, reviewed PFAS drinking water occurrence data collected as part of the UCMR 3 and state-led monitoring efforts, and considered public comments received. The EPA finds that oral exposure to PFHxS, HFPO-DA, or PFNA individually may lead to adverse health effects in humans; that each of these three PFAS have a substantial likelihood of occurring in finished drinking water with a frequency and at levels of public health concern; and that, in the sole judgment of the Administrator, regulation of PFHxS, HFPO-DA, and PFNA individually presents a meaningful opportunity for health risk reductions for persons served by PWSs. The EPA is setting the individual MCLGs for HFPO-DA, PFHxS, and PFNA at 10 ng/L (ppt) for each of these three PFAS based on information about each chemical's toxicity (i.e., RfD or minimal risk level) and exposure (i.e., drinking water intake rate or exposure factor; and relative source contribution, which is the proportion of a person's total exposure to the PFAS that is attributed to drinking water) (USEPA, 2024h). The MCLG for each of these individual PFAS is set, as defined in Section 1412(b)(4)(A) of the SDWA, at "the level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety" (USEPA, 2024h).

The agency is deferring the final individual regulatory determination for PFBS to further consider whether occurrence information supports a finding that there is substantial likelihood that PFBS will individually occur in PWSs and at a level of public health concern. Therefore, no individual MCLG for PFBS is being established at this time. However, when evaluating PFBS in mixture combinations with PFHxS, PFNA, and/or HFPO-DA, the EPA has determined that based on the best available information it does meet all three statutory criteria for regulation when a part of these mixtures, including that it is anticipated to have dose-additive adverse health effects (see sections III.B and IV.B.1 of preamble); there is a substantial likelihood of its co-occurrence in combinations with PFHxS, PFNA, and/or HFPO-DA with a frequency and at levels of public health concern (see sections III.C, VI.C, VI.D of preamble) USEPA 2024j); and that there is a meaningful opportunity for health risk reduction by regulating mixture combinations of these four PFAS (see section III.D of preamble). Therefore, although the agency is deferring the individual final regulatory determination for PFBS, PFBS is included in the final determination to regulate mixture combinations containing two or more of PFHxS, PFNA, HFPO-DA, and PFBS. The establishment of individual MCLGs for PFHxS, PFNA, and HFPO-DA as well as a Hazard Index MCLG for mixtures of two or more of PFHxS, PFNA, HFPO-DA, and PFBS addresses potential health risks related to individual PFAS exposure as well as dose additive adverse health effects from exposure to mixtures of two or more of these four PFAS.

Suffolk County Water Authority (SCWA) (Doc. #1589, SBC-043705)

Establishing an MCLG for the four other subject PFAS that is greater than zero is also important information for public water suppliers. For the SCWA, this means that it does not necessarily need to treat these four PFAS to non-detectable levels in order to achieve the goal of having no adverse effect on the health of its customers. Instead, it only has to achieve the MCLG with an adequate margin of safety for operational purposes, typically half the MCLG.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. In the context of the MCLG, an adequate margin of safety is incorporated into the MCLG, as indicated by Section 1412(b)(4)(A) of the SDWA, which states that the MCLG is set at "the level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety." The EPA notes that regulated PWSs must take action to reduce PFAS concentrations to meet or be below the MCLs; the MCLGs are non-enforceable public health goals. Public water suppliers must treat water to the MCL for a given contaminant. MCLs are set as close to MCLGs as feasible.

Aidan Cecchetti (Doc. #1640, SBC-044364)

• EPA requests comment on whether the HBWCs should instead be proposed as stand-alone MCLGs in addition to or in lieu of the mixture MCLGs. EPA requests comment on whether establishing a traditional MCLG and MCL for PFHxS, HFPODA, PFNA, and PFBS instead of, or in addition to, the HI approach would change public health protection, improve clarity of the rule, or change costs (pg. 18671 Federal Register Volume 88, Number 60).

The commenters agree with the EPA's decision not to propose the HBWCs for PFHxS, HFPO-DA, PFNA, and PFBS as stand-alone MCLGs. The commenters agree with the EPA determination that promulgation of individual MCLGs and MCLs for those contaminants would provide less public health protection than regulating these contaminants using the HI approach. Regulating these contaminants with individual MCLGs and MCLs would provide greater clarity and lower costs for public water systems but would not account for potential additive adverse health effects of contaminant mixtures. The commenters agree with the EPA determination to regulate these contaminants using the HI approach without individual MCLGs or MCLs. The commenters do not see the value to producing MCLGs for these contaminants in addition to the HI approach.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. The EPA disagrees with the commenter that there is no value in deriving individual MCLGs in addition to the Hazard Index MCLG. After a review of public comments, the agency is promulgating individual MCLs for PFHxS, PFNA, and HFPO-DA in addition to the Hazard Index MCL for mixtures containing two or more of these PFAS and PFBS. For additional discussion on the establishment of stand-alone standards in lieu of or in addition to the

Hazard Index MCL, please see section 5.3 of the EPA response in this *Response to Comments* document.

New Jersey Department of Environmental Protection (NJDEP) (Doc. #1699, SBC-045024)

Hazard Index for PFHxS, HFPO-DA, PFNA, and PFBS

EPA requested comments on the proposed use of an HI approach for PFHxS, HFPO–DA, PFNA, and PFBS, including whether it can be clearly implemented and achieves the goal of protecting against dose additive noncancer health effects. As discussed in the comments above, NJDEP agrees that the proposed HI approach is protective for dose additive non-carcinogenic effects of the four PFAS that are included in the HI. NJDEP recommends the EPA continue to evaluate the potential addition of additional PFAS to the HI as appropriate.

Regarding whether establishing traditional MCLs for PFHxS, HFPO–DA, PFNA, and PFBS instead of, or in addition to, the HI approach as stated above, use of stand-alone MCLs in lieu of the mixture HI would not account for additive toxicity when mixtures of these PFAS are detected in drinking water. Use of stand-alone MCLs in addition to the mixture HI would have no practical impact, since an exceedance of the HBWC for a specific PFAS would result in an HI above 1.0 even if none of the other PFAS included in the HI are detected.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. There may be a practical impact of these individual MCLs (for PFHxS, PFNA, and HFPO-DA) where one of these three PFAS occur in isolation (i.e., without one of the other four Hazard Index PFAS present) above their individual MCLs. The EPA notes that this regulatory structure is consistent with the intended effect of the proposed regulation, where as proposed, a single PFAS found in drinking water at a concentration above its HBWC would have caused an exceedance of the MCL. Based on public comment, the EPA has restructured the rule such that two or more of these regulated PFAS would be necessary to cause an exceedance of the Hazard Index and instead will regulate individual exceedances of PFNA, PFHxS, and HFPO-DA as individual MCLs to improve risk communication. Risk communication is an important focus for water systems and the EPA believes that finalizing individual MCLs for PFHxS, PFNA, and HFPO-DA can support risk communication as utilities and the public may be more familiar with this regulatory framework. Additionally, the final individual MCLs for PFHxS, PFNA, and HFPO-DA will address and communicate health concerns for these compounds where they occur in isolation. At the same time, since those individual MCLs do not address additional risks from co-occurring PFAS, the EPA is finalizing a Hazard Index MCL that provides a framework to address and communicate dose additive health concerns associated with mixtures of PFHxS, PFNA, HFPO-DA, and PFBS that co-occur in drinking water. For the EPA's discussion on the establishment of stand-alone standards in lieu of or in addition to the Hazard Index MCL, please see section 5 of the EPA response in this *Response to Comments* document.

New Jersey Department of Environmental Protection (NJDEP) (Doc. #1699, SBC-045019)

As discussed in the proposed rule, the general HI approach, which considers non-carcinogenic toxicological effects in both the same and different target organs, is more protective than the target organ specific HI or RFP approaches, which only consider effects in the same target organ. As discussed in the proposed rule, while the general HI approach requires more assumptions than the target organ HI or RPF approach, there is often insufficient information (e.g., lack of target organ-specific toxicity factors) for use of the target specific HI or RPF approach. As such, as stated by EPA (p.18655) the choice of the general HI approach is a "reasonable policy choice for regulating a mixture of chemicals that are expected to adversely impact multiple health endpoints." As stated in the proposed rule the general HI approach "is protective against all health effects across component chemicals and therefore meets the statutory requirements of establishing an MCLG under SDWA."

EPA Response: This commenter supports the EPA's approach.

Public Health, Seattle & King County (PHSKC) (Doc. #1594, SBC-042353)

Yet PHSKC also supports the mixtures approach that EPA has taken for PFAS chemicals that frequently occur as mixtures and where health risks may be greater with exposures to multiple PFAS, as with GenX, PFABS, PFNA and PFHxS.

EPA Response: The commenter supports the EPA's approach.

Environmental Protection Network (EPN) (Doc. #1773, SBC-043859)

EPN finds that EPA's analysis of UCMR3 data and state data provides convincing evidence that these four PFAS chemicals co-occur in public water systems serving millions of people at a frequency justifying use of a mixtures approach. EPN agrees with EPA's statement that there should not be a bright line threshold for occurrence in drinking water that triggers whether a contaminant is a public health concern justifying a national drinking water standard. In addition to frequency of occurrence, the potency of the chemical, geographic distribution, impacted population, and type of health effects should be considered in deciding whether to regulate a drinking water contaminant. Based on all of those factors, EPN agrees that a HI of one is an appropriate MCLG indicating no appreciable risk.

EPA Response: The commenter supports the EPA's approach.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-044032)

14. EPA requests comment on whether establishing a traditional MCLG and MCL for PFHxS, HFPO-DA, PFNA, and PFBS instead of, or in addition to, the HI approach would change public health protection, improve clarity of the rule, or change costs.

a. See number 4. CWUC is in support of establishing MCLs for any additional PFAS parameters.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-044030)

12. EPA requests comment on its proposal of using an HI approach for PFHxS, HFPO-DA, PFNA, and PFBS, including whether it can be clearly implemented and achieves the goal of protecting against dose additive noncancer health effects.

a. See number 4. CWUC is more supportive of EPA establishing MCLs for these parameters.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-044023)

6. EPA requests comment on whether the HBWCs should instead be proposed as stand-alone MCLGs in addition to or in lieu of the mixture MCLGs.

a. See number 4. Having a mixture MCL/G is problematic for communicating health effects language to our customers.

b. CWUC is in support of using the HBWCs to establish the MCLs for the four additional PFAS constituents.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Also, for the EPA response to the comment about communicating health effects language to customers, please see section 5.3 of this *Response to Comments* document.

PFAS Project Lab (Doc. #1786, SBC-044714)

The need for federal MCLs

EPA has long been aware of the scientific evidence pointing to harm from low-dose exposure to PFOA and PFOS, and regulations for these two compounds are long overdue. For example, EPA documented evidence of PFOA's carcinogenicity in its 2016 Health Effects Support Document, and following studies have strengthened that finding. Moreover, the scientific evidence supports regulating additional PFAS, including PFHxS, HFPO-DA, PFNA, and PFBS, and it is thus critical that they also be included. In 2021, ATSDR conducted a comprehensive assessment of PFHxS and PFNA in its toxicological profile for perfluoroalkyls, and it is justified that EPA uses the derived Minimum Risk Levels for these two compounds.

EPA Response: The commenter agrees with the EPA's approach.

Fairfax Water (Doc. #1789, SBC-045296)

EPA's proposal to use a Hazard Index calculation for PFNA, PFHxS, PFBS, and HFPO¬DA is an approach that has never been used under the Safe Drinking Water Act. The approach combines PFAS compounds with different health endpoints. Utilities could exceed the HI even if each PFAS compound is below the limits of health impacts. Further, the HI approach will be challenging to communicate to the public. Instead of the HI approach, EPA should establish MCL's for these PFAS compounds using reference doses (RIDs) and human health toxicity assessments when they are available.

EPA Response: Please see sections 4.3.1, 4.3.2, and 1.2 of the EPA response in this *Response to Comments* document.

Nebraska Department of Environment and Energy (NDEE) (Doc. #1653, SBC-043205)

The Department suggests disregarding the Hazard Index as this may lead to unnecessary and costly treatment for public water systems.

EPA Response: Please see sections 4.3.2 and 13, including section 13.3.2 (HFPO-DA, PFNA, PFBS National Costs), of the EPA response in this *Response to Comments* document.

Kevin Korro (Doc. #1538, SBC-042655)

In addition, I admire the use of the hazard index (HI) approach to protect against mixtures of PFHxS, HFPO-DA and its ammonium salts, PFNA, and PFBS in drinking water, with an HI of 1.0 being proposed as the MCLG for these four PFASs and any mixture containing one or more of them. This is something that I find very admirable. This is something that gives me a lot of cause for optimism.

On the other hand, I would like to suggest the MCLGs that have been proposed be made more severe to offer the maximum possible degree of protection for public health. It has been demonstrated beyond a reasonable doubt that PFAS are harmful and that they represent a risk to human health even when present in very low amounts. I would like to make it clear that I highly encourage the EPA to take into consideration making more cuts to the MCLG before they finalize the regulation.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Additionally, SDWA requires that to the degree that the EPA's action is based on science, the EPA must use "the best available, peer reviewed science" and "data collected by accepted methods or best available methods." The HBWCs/MCLGs are based on the best available science and data collected by accepted methods (see section III in the preamble and USEPA, 2024h). Specifically, peer-reviewed, publicly available toxicity assessments are available for HFPO-DA (USEPA, 2021e), PFBS (USEPA, 2021d), PFNA (ATSDR, 2021), and PFHxS (ATSDR, 2021) that provide the oral toxicity values (i.e., RfD or minimal risk level) used to calculate the HBWCs; the EPA selected the corresponding DWI-BW for the relevant sensitive population or life stage from the Exposure Factors Handbook (USEPA, 2019) based on the best

available, peer-reviewed science taking into account the relevant sensitive population(s) or life stage(s); and the RSCs are based on the best available, peer-reviewed science or best available methods taking into account the relevant sensitive population(s) or life stage(s) (USEPA, 2000d). The commenter did not present any information to support different values for the HBWCs/MCLGs.

Massachusetts Department of Environmental Protection (MassDEP) (Doc. #1726, SBC-052980)

Application of potency subgroups to the Hazard Index

EPA should consider an alternative approach to calculating the HI based on potency subgroups that differ by factors of 3- or 10-fold rather than the current approach using individual HBWCs described in the Mixture document. The modest differences between the HFPO-DA HBWC of 10 ppt, PFNA HBWC of 10 ppt, and PFHxS HBWC of 9 ppt (10 ppt if calculated as above) for example are not supported as being distinct values given the differences in factors such as database extent, study execution, and inter-lab variability. The use of potency subgroups would better reflect the uncertainty in calculating PFAS drinking water values as well as simplify the calculation of the HI. As an example, for a drinking water system with detections of HFPO-DA, PFNA, and PFHxS, the current approach would require dividing the HFPO-DA drinking water concentration by the HFPO-DA HBWC, the PFNA drinking water concentration by the PFNA HBWC, and the PFHxS drinking water concentration by the PFHxS HBWC. For an approach based on potency subgroups, the HFPO-DA, PFNA, and PFHxS drinking water concentrations would all be divided by the same potency subgroup factor, as the HBWC values do not differ by more than a factor of 3-fold in the current draft Mixture document. This potency subgroup approach should also be applied to additional PFAS if added to the HI approach.

EPA Response: The EPA disagrees that segregating PFAS into potency subgroups that differ by factors of 3- or 10-fold is necessary or preferable. The fact that the HBWCs for HFPO-DA, PFNA, and PFHxS do not differ significantly should not necessarily be construed as a function of relative potency. RfDs (or minimal risk levels) for different PFAS may be derived using different health effects data (e.g., the RfD for HFPO-DA is based on liver effects; the minimal risk level for PFHxS is based on thyroid effects), and may be based upon different study types or dosing schedules (e.g., dietary or drinking water ad libitum versus daily oral gavage), exposure lifestages (e.g., adult versus developmental), and overall hazard evidence bases. Thus, the underpinning toxicity information considered in the assessment and derivation of a human health toxicity reference value from PFAS to PFAS is typically diverse and comes with different qualitative and quantitative uncertainties. Such considerations are directly addressed in the human health assessment for each PFAS, not the subsequent calculation of an HBWC. Further, calculation of HBWCs across PFAS includes other considerations (in addition to those discussed in a health assessment) such as bodyweight-based drinking water intake rates, which may be different (e.g., adult versus early(ier) lifestages) across PFAS mixture components. Using each individual mixture component chemical RfD (or minimal risk level) as the denominator in the calculation of a corresponding HQ is consistent with EPA chemical mixtures guidance and

practice; to aggregate or group based only upon quantitative convergence of HBWCs is unnecessary. In addition, as a practical matter, use of subgroups in the Hazard Index would be more complicated and difficult to communicate and would not result in any quantitative difference to the Hazard Index. In this hypothetical example, the Hazard Index is 4 either way:

The EPA approach:

$$HI\ MCLG\ = \left(\frac{[HFPO-DA_{ng/L}]}{[10\ ng/L]}\right) + \left(\frac{[PFBS_{ng/L}]}{[2000\ ng/L]}\right) + \left(\frac{[PFNA_{ng/L}]}{[10\ ng/L]}\right) + \left(\frac{[PFHxS_{ng/L}]}{[10\ ng/L]}\right)$$
$$=$$

$$HI\ MCLG\ = \left(\frac{[5_{ng/L}]}{[10\ ng/L]}\right) + \left(\frac{[1000_{ng/L}]}{[2000\ ng/L]}\right) + \left(\frac{[12_{ng/L}]}{[10\ ng/L]}\right) + \left(\frac{[20_{ng/L}]}{[10\ ng/L]}\right) = 4$$

Commenter suggested approach:

$$HI\ MCLG\ = \left(\frac{\left[HFPO-DA_{\frac{ng}{L}} + PFNA_{\frac{ng}{L}} + PFHxS_{\frac{ng}{L}}\right]}{[10\ ng/L]}\right) + \left(\frac{[PFBS_{ng/L}]}{[2000\ ng/L]}\right) =$$

$$HI\ MCLG\ = \left(\frac{\left[5\frac{ng}{L} + 12\frac{ng}{L} + 20\frac{ng}{L}\right]}{[10\ ng/L]}\right) + \left(\frac{[1000_{ng/L}]}{[2000\ ng/L]}\right) = 4$$

To assist in the calculation of these values, the agency is developing a calculator tool to easily determine Hazard Index calculations at individual PWSs. After finalization of the PFAS NPDWR, the EPA also intends to provide support to utilities, primacy agencies, and other interested parties to ensure successful rule implementation.

American Water Works Association (AWWA) (Doc. #1759, SBC-045603)

Additionally, the agency's approach is contrary to the agency's own guidance for assessing risks of mixtures, which states that it must be "sufficiently similar mixture" where "components and respective portions exist in approximately the same pattern" (EPA, 1986). As indicated in this guidance, a key feature of a mixture is the mixtures composition and consistent co-occurrence of the components (PFNA, PFHxS, PFBS, and HFPO-DA).

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Aqua America, an Essential Utilities Company (Doc. #1623, SBC-043075)

Combined MCLG for PFNA, PFHxS, HFPO-DA, and PFBS

According to the Proposal, EPA is proposing to establish a combined MCLG for four PFAS set at a hazard index (HI) of 1.0. In proposing this MCLG, EPA is making several key scientific determinations to support this decision:

1. PFNA, PFHxS, HFPO-DA, and PFBS are likely to co-occur in water in a way that is a "sufficiently similar mixture,"

2. Co-exposure to a mixture of PFNA, PFHxS, HFPO-DA, and PFBS can lead to an aggregate health effect because of dose additivity, and

3. The dose additivity of PFAS can be applied through the hazard index with dissimilar health effects, or outcomes.

Aqua supports the Agency's interest in taking a public health protective stance on PFAS. However, EPA's assumption of dose additivity without sufficient evidence of the contrary is flawed. There are numerous concerns regarding the Agency's determination that these compounds co-occur and that their co-exposure has a dose-additive effect on dissimilar outcomes.

Aqua is concerned that the Agency's approach is contrary to the Agency's own guidance for assessing risks of mixtures, which states that it must be "sufficiently similar mixture" where "components and respective portions exist in approximately the same pattern." As indicated in this guidance, a key feature of a mixture is the mixtures composition and consistent co-occurrence of the components (PFNA, PFHxS, PFBS, and HFPO-DA). The EPA's occurrence analysis fails to sufficiently document co-occurrence of this mixture of PFAS.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. The EPA disagrees with the commenter's claims that the EPA is making the determination that PFNA, PFHxS, HFPO-DA, and PFBS are likely to co-occur in water in a way that is a "sufficiently similar mixture." Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Additionally, the EPA disagrees with the commenter's claim that the EPA's occurrence analysis fails to sufficiently document co-occurrence of these PFAS in drinking water. The EPA's evaluation of UCMR 3 data as well as data from state-led drinking water monitoring efforts shows that PFHxS, PFNA, and HFPO-DA each have a substantial likelihood to occur in finished drinking water and that these three PFAS and PFBS are also likely to co-occur in mixtures (USEPA, 2024j). Please see sections III and VI in the preamble and sections 3 and 7 of the EPA response in this *Response to Comments* document for additional discussion.

Environmental Protection Network (EPN) (Doc. #1773, SBC-043854)

EPN recommends the use of a HI for the drinking water standard in addition to individual MCLGs and MCLs because the HI accounts for dose additivity and is thus more health protective. We believe EPA should account for dose additivity in order to comply with SDWA's requirement to set drinking water standards with an adequate margin of safety. We recommend that EPA also provide individual MCLGs and MCLs for the four chemicals to improve rule clarity and maintain consistency with previous drinking water standards. EPN recommends against adding PFOA and PFOS to the HI because these chemicals differ from the other four PFAS chemicals in having MCLGs of zero, a level well below analytical quantitation levels, and their addition would obscure the risks posed by the four more-recently manufactured PFAS chemicals.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Washington State Department of Health (DOH) (Doc. #1665, SBC-044416)

Page 18730. EPA requests comment on whether establishing a traditional MCLG and MCL for PFHxS, HFPO–DA, PFNA, and PFBS instead of, or in addition to, the HI approach would change public health protection, improve clarity of the rule, or change costs.

• DOH supports using both the traditional and HI approach for MCLs.

• These chemicals frequently occur in mixtures. When two or more are present, the HI approach effectively lowers the acceptable limit for each. Since PFAS health impacts are likely additive, a combined standard is appropriate.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Washington State Department of Health (DOH) (Doc. #1665, SBC-044409)

EPA requests comment on the general HI approach for the mixture of four PFAS.

• DOH supports the HI approach.

EPA requests comments on the merits and drawbacks of the target- specific HI or RPF approach.

• DOH supports the HI approach.

EPA Response: This commenter supports the EPA's approach.

Association of Metropolitan Water Agencies (AMWA) (Doc. #1738, SBC-045950)

Section 2.2: PFAS mixture of PFBS, PFNA, GenX, PFHxS

AMWA recognizes the difficulty of addressing a class of compounds that includes thousands of chemicals with many uncertainties. PFOA and PFOS, being some of the most studied and well-known of the PFAS class, have individual proposed MCLGs while the additional four PFAS are proposed to be addressed as a mixture. EPA has proposed using a hazard index (HI) approach for PFBS, PFNA, GenX, and PFHxS, with an HI of 1.0 for the MCLG.

There have been past rulemakings when EPA has used the sum of certain chemicals in regulation. For example, in the Stage 2 Disinfectants and Disinfection Byproducts Rule, trihalomethanes (THMs) and haloacetic acids (HAA5) have an MCL for the sum of certain chemicals in these groups. The HI proposed by EPA is slightly different, as it uses a quotient of measured concentration in drinking water over a Health Based Water Concentration (HBWC). EPA proposes this measure to address the additive noncancer health effects of these compounds in a mixture. EPA declined to implement individual MCLGs for each compound, which AMWA is supportive of, as more data is needed for these chemicals to proceed with individual MCLGs.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. For the EPA's discussion on the establishment of stand-alone MCLs for PFHxS, HFPO-DA, and PFNA in addition to the Hazard Index MCL, please see section 5 of the EPA response in this *Response to Comments* document. The health information available for PFHxS, PFNA, and HPFO-DA is sufficient to calculate individual MCLGs for each of these PFAS.

Cleveland Water, City of Cleveland, Ohio (Doc. #1672, SBC-044902)

Section 2.2: PFAS mixture of PFBS, PFNA, GenX, PFHxS

Cleveland Water recognizes the difficulty of addressing a class of compounds that includes thousands of chemicals with many more unknowns than knowns. PFOA and PFOS, being some of the most studied and well-known of the PFAS class, have individual proposed MCLGs while the additional four PFAS are proposed to be addressed as a mixture. EPA has proposed using a hazard index (HI) approach for PFBS, PFNA, GenX, and PFHxS, with an HI of 1.0 for the MCLG.

There have been past rulemakings when EPA has used the sum of certain chemicals in regulation. For example, in the Stage 2 Disinfectants and Disinfection Byproducts Rule, trihalomethanes (THMs) and haloacetic acids (HAA5) have an MCL for the sum of certain chemicals in these groups. The HI proposed by EPA is slightly different, as it uses a quotient of measured concentration in drinking water over a Health Based Water Concentration (HBWC). EPA proposes this measure to address the additive noncancerous health effects of these compounds in a mixture. EPA declined to implement individual MCLGs for each compound individually, which we are supportive of, as more data is needed individually for these chemicals to proceed with individual MCLGs.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. For the EPA's discussion on the establishment of stand-alone MCLs for PFHxS, HFPO-DA, and PFNA in addition to the Hazard Index MCL, please see section 5 of the EPA response in this *Response to Comments* document. The health information available for PFHxS, PFNA, and HPFO-DA is sufficient to calculate individual MCLGs for each of these PFAS.

Cleveland Water, City of Cleveland, Ohio (Doc. #1672, SBC-052954)

Cleveland Water is concerned that this proposed HI would serve as a de-facto MCL for systems that have detected only one of the PFAS chemicals present in their system. These de-facto MCLs are equal to the HBWC EPA has proposed, but the agency is not officially proposing them as individual MCLs, an action we support. If EPA is addressing the issues these chemicals cause as a mixture and when they co-occur, then it would make sense that a water system would need to have a mixture and co-occurrence (more than one) present to do this calculation.

EPA Response: Please see sections 4.3.2, 3, and 5 of the EPA response in this *Response to Comments* document. The EPA is finalizing a Hazard Index of 1 (unitless) as the MCLG and MCL for any mixture containing two or more of PFHxS, PFNA, HFPO-DA, and PFBS.

Cleveland Water, City of Cleveland, Ohio (Doc. #1672, SBC-052956)

Cleveland Water is concerned that, once we have a holistic view of PFAS occurrence in drinking water from UCMR 5 data, it will become clear this approach may not have been the most appropriate, and more PFAS could potentially be candidates for regulation that do not have the same health effects. The addition of more PFAS to this HI will decrease the quotient threshold each quotient is allowed, without being more protective of public health. For example, right now each PFAS chemical can have a quotient of 0.25 (0.25+0.25+0.25+0.25=1), a value of ¼ of the HBWC and/or health advisories and still be compliant, but if one more PFAS chemical is added to make five, that quotient reduces to 0.2. At some point, the HI of 1.0 will not be attainable with additional PFAS, and EPA will have to evaluate its options on how to group and separate certain PFAS.

EPA Response: The commenter incorrectly interprets the Hazard Index approach as having four HQs equal to 0.25. In fact, HQs will differ across time and space depending on the actual measured concentrations of each of the four component PFAS. Regarding potential addition of PFAS, the EPA's final regulatory determination and final rule are limited to the mixtures that include two or more of PFNA, PFHxS, PFBS, and HFPO-DA. If there is any potential future inclusion of additional PFAS under this approach, such inclusion would be the subject of a potential future regulatory process. Additionally, pertaining to UCMR 5, please see sections 3.1.2 and 6.8 of the EPA response in this *Response to Comments* document. Also, please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

New York State Department of Health (NYS DOH) (Doc. #1677, SBC-044947)

9. The EPA's proposed approach to establish a HI as a way to address the additive health effects of mixtures is precedent setting for drinking water standards and presents implementation challenges. Regulators and public water systems will be required to provide education and communication on the new compliance concept, while also tracking and enforcing PFOA and/or PFOS MCLs in a more traditional way. Based on existing compliance data, the Department does not believe that the added complexity of the HI approach will provide significant additional public health protection, since monitoring conducted in New York State demonstrates that PFAS compounds used to calculate the HI typically co-occur with PFOA and/or PFOS. The Department supports establishing individual MCLs for GenX, PFBS, PFNA and PFHxS. As shown in Table 2, New York State expects 3 water systems to exceed the Hazard Index that do not have PFOA or PFOS greater than 4 ppt.

Table 2: Hazard Index 1m act Assessment

[Table 2: See Docket ID EPA-HQ-OW-2022-0114-1677]

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Also, in response to the comment that the Hazard Index approach is precedent-setting, there is precedent for the Hazard Index approach (see USEPA, 1991c) and that it is supported by the EPA's chemical mixtures guidance (USEPA, 1986; USEPA, 2000b). As noted by the SAB in its review of the EPA's draft PFAS Mixtures Framework, the Hazard Index approach for addressing potential health risks associated with exposure to a mixture of PFHxS, HFPO-DA, PFNA, and/or PFBS "is a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media. The Hazard Index is an approach based on dose additivity (DA) that has been validated and used by EPA" (USEPA, 2022b). Based on the EPA's evaluation of the best available occurrence data, the EPA has determined that there is a substantial likelihood that PFHxS, HFPO-DA, and PFNA individually, as well as mixtures of PFHxS, HFPO-DA, PFNA, and/or PFBS, will occur/co-occur in PWSs with a frequency and at levels of public health concern (see also sections 3.1.2, 3.2.2, and 6.3 of the EPA response in this *Response to Comments* document). Furthermore, the EPA disagrees that the Hazard Index will not provide significant additional public health protection or that regulation of PFOA and PFOS will protect against exposures to the Hazard Index PFAS. Please see the EPA response to comment Doc. #1686, SBC-043823 in section 3.1 in this *Response to Comments* document.

City of Vancouver Water Utility, Vancouver, WA (Doc. #1684, SBC-044309)

The hazard index approach for the PFAS other than PFOA and PFOS has never been used in setting an MCL, and it presents both technical and legal questions regarding its scientific basis as a health risk indicator. There is limited understanding of risk at these levels when these PFAS are combined together. EPA's Reference Dose for PFNA, GenX Chemicals, PFHxS, and PFBS is based entirely on laboratory animal studies, even though EPA itself advises "Adequate human

data are the most relevant for assessing risks to humans." Using a method that could ultimately cost rate payers billions of dollars with limited scientific basis is not acceptable per the Safe Drinking Water Act, which requires consideration of the costs and benefits. There is no way to determine the appropriate cost or benefits if limits are placed on these four PFAS utilizing the proposed hazard index approach. A traditional MCLG and MCL approach would improve clarity.

The shorter chain PFAS proposed in the HI break through current filtration treatment technologies (IX and GAC) significantly faster than longer chain PFAS like PFOS and PFOA. Setting a hazard index of 1.0 will have a significant cost impact on the ongoing O&M costs to ratepayers and it is essential that adequate data is collected to ensure an appropriate MCL is set if the HI approach is used for short chain PFAS. Did the EPA include the impacts of such a low hazard index when completing its benefit/cost analysis?

Provision must be placed in the rule to ensure additional PFAS cannot be randomly added to the hazard index calculation without following the required processes.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Also, with respect to the use of animal studies, SDWA requires that to the degree that the EPA's action is based on science, the EPA must use "the best available, peer reviewed science" and "data collected by accepted methods or best available methods." The HBWCs/MCLGs are based on the best available science and data collected by accepted methods (see section III in the preamble and USEPA, 2024h). Specifically, peer-reviewed, publicly available toxicity assessments are available for HFPO-DA (USEPA, 2021e), PFBS (USEPA, 2021d), PFNA (ATSDR, 2021), and PFHxS (ATSDR, 2021) that provide the oral toxicity reference values (i.e., RfD or minimal risk level) used to calculate the HBWCs; the EPA selected the corresponding DWI-BW for the relevant sensitive population or life stage from the Exposure Factors Handbook (USEPA, 2019) based on the best available, peer-reviewed science from publicly available, peer-reviewed studies taking into account the relevant sensitive population(s) or life stage(s); and the RSCs are based on the best available, peer-reviewed science or best available methods taking into account the relevant sensitive population(s) or life stage(s) (USEPA, 2000c). Additionally, as noted in the EPA's *Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a) and *A Review of the Reference Dose and Reference Concentration Process* (USEPA, 2002a), animal studies can provide the basis for toxicity reference values when adequate human studies are not available.

For the EPA response to comments about the addition of PFAS to the Hazard Index calculation, please see section 4.3.5 of the EPA response in this *Response to Comments* document.

For the EPA response to comments about technical, scientific, and legal questions related to an MCL based on the Hazard Index approach, and comments related to cost, please see sections 5 and 13 of the EPA response in this *Response to Comments* document.

After considering public comments, the EPA has established individual MCLGs and MCLs for three of these PFAS in addition to the Hazard Index MCLG and MCL. For the EPA's discussion on the establishment of stand-alone MCLs for PFHxS, HFPO-DA, and PFNA in addition to the

Hazard Index MCL, please see section 5.2 of the EPA response in this *Response to Comments* document.

Wisconsin Department of Natural Resources (Doc. #1828, SBC-044801)

Hazard Index

WDNR supports the use of the hazard index for the four proposed PFAS. The hazard index approach is used in Wisconsin and our Drinking Water System database is programmed to calculate the index automatically when analytical results are submitted. The hazard index is a good method to weigh the risks to human health of both individual chemicals as well as mixtures.

EPA Response: This commenter supports the EPA's approach.

Wisconsin Department of Justice et al. (Doc. #1687, SBC-044447)

3. EPA's proposed Hazard Index approach to regulate PFHxS, GenX, PFNA, and PFBS is appropriate and justified to address the demonstrated adverse health effects of PFAS mixtures.

As previously discussed, infra at Comment 1.a., EPA's decision to regulate PFHxS, GenX, PFNA, and PFBS using a Hazard Index approach is amply supported by, among other studies, health effect studies concerning each chemical individually and from PFAS mixtures. As a result, EPA's Hazard Index approach, a method that employs a numerical value used in risk assessment to estimate the potential health risks associated with exposures to multiple chemicals or contaminants. The Hazard Index is determined by adding up the ratio of the concentration detected in drinking water to the HBWC for each of the four PFAS included in the Hazard Index. Here, the Hazard Index provides a scientifically sound way to evaluate the cumulative effects of exposure to the four subject PFAS and helps to determine whether the combined risk from multiple exposures is within acceptable levels or if further action is needed to protect human health. A Hazard Index greater than 1.0 indicates that the combined exposures may pose a potential risk to human health, while an index less than 1.0 suggests that the risks are likely to be low.

EPA's proposed use of a Hazard Index in this situation—where human exposure to a mixture of PFAS in drinking water is occurring simultaneously—is scientifically and technically sound and appropriate. Many States use Hazard Indices to address the risks of exposure to a mixture of contaminants. [FN38: Examples of states using Hazard Indices to assess the combined risk of mixtures of contaminants include: California (see https://dtsc.ca.gov/faq/how-are-the-toxicity-criteria-used-at-california-hazardous-waste-and-hazardous-substance-release-sites/); Minnesota (seehttps://www.health.state.mn.us/communities/environment/risk/guidance/gw/additivity.html); Oregon (see https://www.oregon.gov/deq/aq/cao/Documents/CAO-HIQuickLearn.pdf) and Wisconsin (see https://www.dhs.wisconsin.gov/publications/p03212.pdf).] In fact, one of the undersigned—Wisconsin—is currently using Hazard Indices for assessment of the hazards posed

by a mixture of PFAS in drinking water and has released an informative video describing its function. [FN39: See Wisconsin DHS, PFAS Hazard Index (March 2022), https://www.youtube.com/watch?v=vWyQgP7F0mM; see also https://www.dhs.wisconsin.gov/publications/p03212.pdf.] EPA's approach is well accepted both by regulators throughout the United States and by the scientific community and is appropriate and justified in addressing the demonstrated potential adverse health effects of PFAS mixtures in drinking water.

EPA Response: This commenter supports the EPA's approach.

Minnesota Center for Environmental Advocacy et al. (Doc. #1707, SBC-045724)

B. EPA Correctly Chose the Use a Hazard Index to Regulate Multiple PFAS Together

The Commenters also write to express their full support for the Agency's decision to use a Hazard Index to regulate PFHxS, GenX Chemicals, PFNA, and PFBS. While these PFAS pose serious risks to public health individually, the Hazard Index responds to the reality that these specific PFAS are commonly found together, and that the combination of these PFAS in drinking water poses elevated risks to human health. The Hazard Index is a simple dose additivity tool that safeguards against drinking water supplies contaminated with low concentrations of multiple PFAS.

In the East Metro, MDH has identified public and private drinking water supplies contaminated with low concentrations of PFHxS, PFNA, PFBS, and various other PFAS. [FN39: See PFAS Testing of Minnesota Community Water Systems, Minn. Dep't of Health, https://mdh.maps.arcgis.com/apps/MapSeries/index.html?appid=63515695237f425ea7120d1aac1fd09a (identifying water supply testing locations and results).] To ensure residents are protected from low levels of multiple PFAS substances, MDH uses a Health Risk Index ("HRI") to evaluate the "additive" risk of a group of PFAS that have similar adverse health impacts. [FN40: Minn. Pollution Control Agency & Minn. Dep't of Natural Res., Conceptual Drinking Water Supply Plan 25 (Aug. 2021), available at https://3msettlement.state.mn.us/sites/3msettlement/files/2023-02/Final-Planchapters-1-10.pdf.] In cities like Cottage Grove, multiple wells exceeded the HRI, prompting city officials to remove those wells from the water supply to ensure residents were not drinking toxic water. [FN41: Id. At 34.] Without the HRI, it is possible that the concentrations of individual PFAS substances present in the wells would not trigger an exceedance, meaning that the water would be considered "safe to drink" by regulators. But as MDH and EPA know, the additive risk of low concentrations of multiple PFAS is a serious threat to public health. The regulations must therefore be crafted to respond to this unique risk.

An HRI or Hazard Index does just that. It adds an additional layer of needed security to ensure the safety of our nation's drinking water. EPA is correct to use a Hazard Index to regulate this group of four PFAS compounds together

EPA Response: This commenter supports the EPA's approach.

American Chemistry Council (ACC) (Doc. #1711, SBC-044460)

[The Agency's proposal suffers from the following significant shortcomings –]

• The use of a hazard index (HI) as a basis for the MCL and MCLG Goal for the four other PFAS is unprecedented and contrary to Agency policy and the advice of the Agency's own Science Advisory Board

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-044808)

[The Agency's proposal suffers from the following significant shortcomings –]

• The use of a hazard index (HI) as a basis for the MCL and MCLG Goal for the four other PFAS is unprecedented and contrary to Agency policy and the advice of the Agency's own Science Advisory Board,

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-044817)

[As outlined in these comments, the Agency's proposal suffers from a number of significant shortcomings, including the following –]

• The use of an HI as a basis for the MCL and MCLG Goal for PFBS, HFPO-DA, PFHxS, and PFNA is unprecedented and contrary to Agency policy and the advice of the Agency's own Science Advisory Board,

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Monte Vista Water District (MVWD) (Doc. #1718, SBC-043537)

Methodology

Testing water for PFAS can be complex and requires laboratory analysis, specialized equipment, and expertise to identify and measure specific PFAS compounds in the water sample. MVWD, a small water system, collects water samples which are then tested by a third-party laboratory with results returned to MVWD. Incorporating a Hazard Index (HI) to assess the potential health risks associated with exposure to multiple contaminants in water would require various components of data be factored into the laboratory data received: toxicological assumptions (and their impact on

certain populations), cumulative effects (how contaminants interact with each other), and sensitivity of population (variability in individual susceptibility to contaminants). The HI is based on scientific principles but should be considered a screening tool rather than a definitive measure of health effects. The HI has limitations and should be interpreted with caution. The HI assumes an additive effect of the contaminants, which may not accurately reflect the real-world interactions and complexities of chemical mixtures. Additionally, the HI relies on certain assumptions, such as the reference doses as thresholds for adverse effects and the absented of threshold effects for some contaminants.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Environmental Working Group (EWG) (Doc. #1721, SBC-045410)

The hazard index is a critical tool to address cumulative risks from mixtures of PFAS.

While the EPA set numerical levels as the maximum contaminant levels for PFOA and PFOS at 4 parts per trillion, the EPA applied a unitless hazard index of 1 to the other four PFAS. The EPA took this approach to protect the public from mixtures of GenX, PFBS, PFHxS, and PFNA, or the HI PFAS, "because of their known and additive toxic effects and occurrence and likely cooccurrence in drinking water."[FN26: Id. At 18639.]

As the EPA explains, a hazard index is "a commonly used risk management approach for mixtures of chemicals."[FN27:Id.] Under this approach, the EPA plans to calculate each PFAS's "hazard quotient," by dividing "an exposure metric," (in this case the amount measured in drinking water) by "a health reference value" (in this case the Health Based Water Concentrations the EPA has established for each of the four PFAS). [FN28:Id.] The hazard quotients, or ratios, for each PFAS are then "summed across the mixture to yield the [hazard index]", with a hazard index above 1 indicating increased risk to human health. [FN29:Id.]

The hazard index is a sound and practical approach for establishing an MCL and hazard indices have long been used by other EPA offices and endorsed by leading scientific authorities, including EPA's Science Advisory Board, as "a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media."[FN30:Id.] The hazard index is extensively discussed in the EPA's Guidelines for Health Risk Assessment of Chemical Mixtures, first released in 1986. [FN31: Guidelines for the Health Risk Assessment of Chemical Mixtures, 51 Fed. Reg. 34014 (Sept. 24, 1986).] The EPA regularly applies hazard indices under the Comprehensive Environmental Response, Compensation, and Liability Act to address exposures to multiple substances at a contaminated site and develop clean-up thresholds. [FN32: See Risk Assessment Guidance for Superfund: Volume I Human Health Evaluation Manual (Part A) at 8-11 – 8- 13 ("At most Superfund sites, one must assess potential health effects of more than one chemical … Estimating risk or hazard potential by considering one chemical at a time might significantly underestimate the risks associated with simultaneous exposures to several substances … To assess the overall potential

for noncarcinogenic effects posed by more than one chemical, a hazard index (HI) approach has been developed based on EPA's (1986b) Guidelines for Health Risk Assessment of Chemical Mixtures.") See also Earthjustice et al., supra note 7, at 13-15.] Hazard indices are also used under the Clean Air Act to calculate risk from groups of chemicals emitted from the same source category. [FN33: See National Emissions Standards for Hazard Air Pollutants: Cyanide Chemicals Manufacturing Residual Risk & Technology Review, 86 Fed. Reg. 3910-11 (Jan. 15, 2021).] As Earthjustice, the Natural Resources Defense Council, and other organizations point out in group comments filed to this docket:

hazard indices address the potential for 'low levels of multiple [chemicals] that individually would not likely result in adverse health effects … to result in adverse health effects' when combined in a mixture. This approach to calculating risk – also known as dose additivity – 'has found widespread acceptance as an assessment concept for combined exposures to multiple chemicals … and is extensively used by regulatory authorities as a protective default approach.'[FN34: See Earthjustice et al., supra note 7, at 19 (citing OECD, Considerations for Assessing the Risks of Combined Exposure to Multiple Chemicals: Series on Testing and Assessment No. 296, (Dec. 6, 2018), https://www.oecd.org/chemicalsafety/risk-assessment/considerations-for-assessing-the-risks-of-combined-exposure-to-multiple-chemicals.pdf).]

The hazard index pr449pposedhis rule aligns with a growing scientific movement to address cumulative risks from exposure to mixtures of environmental contaminants. The EPA has identified cumulative impacts research as "a priority to bolster the scientific basis for identifying actions that can improve community health and well-being"[FN35:ENV'T PROT. AGENCY, CUMULATIVE IMPACTS RESEARCH: RECOMMENDATIONS FOR EPA'S OFFICE OF RESEARCH AND DEVELOPMENT (2022) https://www.epa.gov/healthresearch/cumulative-impacts-research#Cumulative%20Impacts%20Report.] and dedicated funding to the "development of innovative approaches to assess the toxicity of chemical mixtures."[FN36: Env't Prot. Agency, Development of Innovative Approaches to Assess the Toxicity of Chemical Mixtures Request for Applications (RFA), https://www.epa.gov/research-grants/development-innovative-approaches-assess-toxicity-chemical-mixtures-request (last updated May 30, 2023).] The EPA also recently released draft principles of cumulative risk assessment under the Toxic Substances Control Act to address risks from mixtures of chemicals. [FN37: ENV'T PROT. AGENCY, DRAFT PROPOSED PRINCIPLES OF CUMULATIVE RISK ASSESSMENT UNDER THE TOXIC SUBSTANCES CONTROL ACT (2023), https://www.epa.gov/system/files/documents/2023-02/Draft%20Principles%20of%20CRA%20under%20TCSA_0.pdf.] In 2011, the European Chemicals Agency released an opinion and guidance document on toxicity and assessment of chemical mixtures,[FN38: EUROPEAN COMM'N, SCI. COMM. ON HEALTH & ENV'T RISKS, SCI. COMM. ON EMERGING & NEWLY IDENTIFIED RISKS, SCI. COMM. ON CONSUMER SAFETY, TOXICITY AND ASSESSMENT OF CHEMICAL MIXTURES (2011) https://ec.europa.eu/health/scientific_committees/environmental_risks/docs/scher_o_155.pdf.] and in 2019 the European Food Safety Authority released guidance on risk assessment of

combined exposures from multiple chemicals. [FN39: Simon John More et al., Guidance on Harmonised Methodologies for Human Health, Animal Health and Ecological Risk Assessment of Combined Exposure to Multiple Chemicals, EFSA JOURNAL (2019) https://www.efsa.europa.eu/en/efsajournal/pub/5634.]

For the four HI PFAS, the hazard index is a meaningful opportunity to address combined risks from the four PFAS which national monitoring data suggest are substantially likely to "occur and co-occur with a frequency of public health concern."[FN40: PFAS National Primary Drinking Water Regulation Rulemaking, 88 Fed. Reg. 18638, 18647 (March 29, 2023).] These four PFAS also pose similar health risks, "individually and in a mixture" such as "adverse effects on several biological systems including the endocrine, cardiovascular, developmental, immune, and hepatic systems" and "are anticipated to affect common target organs, tissues, or systems to produce dose-additive effects from co-exposures."[FN41: Id. At 18645.]

The use of the hazard index is also legally sound. The Safe Drinking Water Act does not specify the form that an MCL or MCLG must take. It only states that an MCLG must be "set at the level at which no known or anticipated adverse effects on the health of persons occur" and that the MCL must be "as close to the maximum contaminant level goal as feasible."[FN42: 42 U.S.C. [sec] 300g-1(b)(4).] In this case, the EPA has set an identical MCL and MCLG for the four HI PFAS by setting a hazard index "level" of 1 for both the MCL and MCLG.

EPA Response: This commenter supports the EPA's approach.

Clean Air Council, et al. (Doc. #1731, SBC-043858)

b. The HI method proposed for PFHxS, HFPO–DA, PFNA, and PFBS is effective and better protects public health than individual MCLs.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Association of Metropolitan Water Agencies (AMWA) (Doc. #1738, SBC-053381)

AMWA is concerned that this proposed HI would serve as a de-facto MCL for systems that have detected only one of the PFAS chemicals present in their system. These de-facto MCLs are equal to the HBWC EPA has proposed, but the agency is not officially proposing them as individual MCLs, an action AMWA supports. If EPA is addressing the issues these chemicals cause as a mixture and when they co-occur, then it would make sense that a water system would need to have a mixture and co-occurrence (more than one) present to do this calculation.

EPA Response: Please see sections 4.3.2, 3, and 5 of the EPA response in this *Response to Comments* document. The EPA is finalizing a Hazard Index of 1 (unitless) as the MCLG and MCL for any mixture containing two or more of PFHxS, PFNA, HFPO-DA and PFBS.

Association of Metropolitan Water Agencies (AMWA) (Doc. #1738, SBC-053383)

AMWA is concerned that once there is a holistic view of PFAS occurrence from UCMR 5 data, it will become clear the HI approach may not have been the most appropriate. The addition of more PFAS to this HI will decrease the quotient threshold each quotient is allowed, without being more protective of public health. For example, right now each PFAS chemical can have a quotient of 0.25 (0.25+0.25+0.25+0.25=1), a value of ¼ of the HBWC and/or health advisories and still be compliant, but if one more PFAS chemical is added to make five, that quotient reduces to 0.2. At some point, the HI of 1.0 will not be attainable with additional PFAS, and EPA will have to evaluate its options on how to group and separate certain PFAS.

Several AMWA utilities, based on their current monitoring data for PFAS, would be in noncompliance based solely on one or more of these PFAS chemicals in the HI. EPA assumes PFOA and PFOS will be the driving force in costs and decisions, but many utilities will have to make decisions primarily on the chemicals included in this HI. This is why EPA must have the best data and information necessary to make the most informed and science-supported decisions.

EPA Response: The commenter incorrectly interprets the Hazard Index approach as having four HQs equal to 0.25. In fact, HQs will differ across time and space depending on the actual measured concentrations of each of the four component PFAS. Regarding potential addition of PFAS, the EPA's final regulatory determination and final rule are limited to the mixtures that include two or more of PFNA, PFHxS, PFBS, and HFPO-DA. If there is any potential future inclusion of additional PFAS under this approach, such inclusion would be the subject of a potential future regulatory process. Also, please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

With respect to the comment about HAs as a basis for HBWCs: HAs are not a pre-requisite for an NPDWR under the SDWA and there is nothing in the statute or the EPA's historical regulatory practice that suggests that the agency must or should delay regulation of a contaminant in order to develop a HA first. Further, the Has for HFPO-DA and PFBS are not a basis or the starting point for their respective HBWCs. The EPA acknowledges that the Has and HBWCs have been set at the same level, but the EPA's HBWCs for HFPO-DA and PFBS represent its conclusions at the time of the rulemaking to calculate the HBWC using identified RfDs, to select the identified DWI-BWs, and apply the RSCs of 0.20.

American Water Works Association (AWWA) (Doc. #1759, SBC-045646)

The proposed approach for the regulation of these compounds includes the development of a hazard index (HI) that is used to determine if the combined levels of 4 PFAS pose a potential health risk. The use of this approach represents the first time a HI approach has been applied for a federal regulation; it has traditionally been applied as a screening tool to make initial decisions regarding chemical remediation. It is also important to note that the approach used by the agency in this case is inconsistent with existing regulatory guidelines; therefore, one of the main focuses of these comments are around the application of a HI outside of a screening approach and the challenges in finding support for this approach in the available science for PFAS.

As the proposed PFAS NPDWR is a significant regulatory action that was submitted to the Office of Management and Budget (OMB) for review, an economic analysis is required under Executive Order 12866. The remaining comments focus on the USEPA's use of the available science related to PFAS exposure and selected endpoints, specifically low birth weight and cardiovascular disease (CVD) to attempt to demonstrate quantifiable and nonquantifiable health risk reduction benefits are likely to occur as the result of compliance with the proposed NPDWR.

EPA Response: Please see sections 4.3.2 and 13 of the EPA response in this *Response to Comments* document.

American Water Works Association (AWWA) (Doc. #1759, SBC-045635)

Finally, the hazard index approach is insufficiently substantiated by occurrence data and toxicological science.

EPA Response: Please see sections 4.3.1, 4.3.2, and 6 of the EPA response in this *Response to Comments* document.

Connecticut Section of the AWWA (CTAWWA) and Connecticut Water Works Association (CWWA) (Doc. #1763, SBC-044237)

Hazard Index

The proposed use of a Hazard Index is difficult to communicate to customers and the general public. Unlike a traditional MCL, the Hazard Index is a calculation and has proved challenging to explain to customers since the proposed PFAS Rule was released. We encourage the EPA to consider traditional MCLs, which would enable utilities and other drinking water professionals including regulators to effectively explain the PFAS Rule to customers.

EPA Response: Please see sections 4.3.2 and 1.2 of the EPA response in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-045676)

ii. The hazard index approach is not appropriate in the regulatory context

The use of the general HI approach as proposed by EPA is contingent on potential exposure information, compound toxicology, and an acceptable noncancer hazard. In short, the general HI method applies principles of human health risk assessment, but in an inherently flawed manner. The science of cumulative risk assessment of chemical mixtures has been the topic of research and policy making for decades, and as it pertains to PFAS, even EPA acknowledged that "there is currently no consensus on whether or how PFAS should be combined for risk assessment purposes" (USEPA 2023, p. 3) as also discussed in Section V.C of the proposed rule. Nonetheless, EPA arbitrarily employs the proposed general HI approach even though, by its own

admission, it is not a consensus method and is contrary to EPA's longstanding guidance and policy related to the application of risk assessment of chemical mixtures.

The general HI method is intended for "screening level" assessments that determine the need for further evaluation, rather than the basis for an expensive and complex NPDWR. In no fewer than three EPA risk assessment guidance documents, EPA refers to the general HI approach as "screening level," including: EPA's Guidelines for Health Risk Assessment of Mixtures (USEPA 1986), Risk Assessment Guidance for Superfund – Part A (USEPA 1989), Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures (USEPA 2000a).

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. The EPA acknowledges that there remains a lack of "consensus on whether or how PFAS should be combined for risk assessment purposes." Under the statute, the EPA must act based on the "best available" science and information. Thus, the statute recognizes that the EPA may act in the face of imperfect information. It also provides a mechanism for the EPA to update standards as more science becomes available. For the PFAS covered by this rule, the EPA concluded that the state of the science and information has sufficiently advanced to the point to satisfy the statutory requirements and fulfill SDWA's purpose to protect public health by addressing contaminants in the nation's PWSs.

Uttara Jhaveri (Doc. #1778, SBC-045443)

EPA's proposal of an MCL for mixtures of PFHxS, HFPO–DA, PFNA, and PFBS expressed as an HI is important when considering the negative impact of PFAS mixtures on human health. [FN14: Id.] The relativity of the PFAS and increase or decrease in levels of certain PFAS may make the HI framework beneficial to inform the protection of human health for any source water PFAS, with available human health assessment values, still in production and use.

EPA Response: This commenter supports the EPA's approach.

Uttara Jhaveri (Doc. #1778, SBC-045444)

Moreover, with the HI approach, additional PFAS can be added over time once more information on health effects, analytics, exposure and treatment is available, and merits additional regulation as determined by EPA. Therefore, the framework is beneficial to address additional PFAS in the future by the Federal and State public health agencies.

EPA Response: The commenter supports the EPA's approach.

Silent Spring Institute (Doc. #1784, SBC-045802)

3. Regulating PFHxS, HFPO-DA, PFNA, and PFBS cumulatively using a hazard index approach is appropriate. It is a practical decision for addressing noncancer effects, and has been previously

applied in numerous regulatory settings such as CERCLA. We recognize the proposed rule as a step in the right direction toward a class-based approach.

We recognize EPA's decision to regulate PFHxS, HFPO-DA, PFNA, and PFBS cumulatively using a hazard index (HI) as a practical decision and likely protective against dose additive noncancer effects. The HI has not been employed in federal drinking water regulations before, which is likely due in large part to the fact that EPA has promulgated very few drinking water standards in the last few decades.

EPA has precedent in grouping chemicals with similar toxicological effects. In fact, the HI is a long- standing practice in EPA's own risk assessment guidelines [REF23: U.S. Environmental Protection Agency. Framework for Estimating Noncancer Health Risks Associated with Mixtures of Per- and Polyfluoroalkyl Substances (PFAS). Washington D.C. 2023.; REF24: U.S. EPA. Guidelines for the Health Risk Assessment of Chemical Mixtures. Washington D.C. 1986.; REF25: U.S. EPA. Risk Assessment guidance for Superfund. Vol. 1. Human Health Evaluation Manual (Part A). Washington D.C. 1991.; REF26: U.S. EPA. Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures. https://cfpub.epa.gov/ncea/risk/recordisplay.cfm?deid=20533. 2000.] and in other federal regulatory programs such as CERCLA. The HI is based on a grouping method that accounts for toxicological similarity while adjusting for relative potencies. EPA has used a similar grouping approach in developing MCLs for trihalomethanes and haloacetic acids, which assume equivalent potencies.

This HI approach also represents an important step forward in addressing PFAS as mixtures of chemicals. Silent Spring Institute supports a class-based approach to addressing PFAS.[REF10: Cordner A, De La Rosa VY, Schaider LA, Rudel RA, Richter L, Brown B. Guideline levels for PFOA and PFOS in drinking water: the role of scientific uncertainty, risk assessment decisions, and social factors. J Expo Anal Environ Epidemiol. 2019.; REF27: Kwiatkowski CF, Andrews DQ, Birnbaum LS, et al. Scientific Basis for Managing PFAS as a Chemical Class. Environ Sci Technol Lett. 2020;7(8):532-543.] Many authoritative state agencies, scholars, scientists, advocacy organizations, professional societies, and regulators in the European Union have upheld the importance of treating PFAS as mixtures of similar chemicals. For example, the American Public Health Association [REF28: American Public Health Association. Reducing Human Exposure to Highly Fluorinated Chemicals to Protect Public Health. 2016.] and a number of expert scientists including Dr. Linda Birnbaum, former head of the National Institute for Environmental Health Sciences, have called for treating PFAS as a class based on their shared chemical properties. Moreover, in 2019, the European Union recommended an action plan to eliminate all non-essential uses of PFAS as a class, indicating regulatory agencies are already moving in this direction.

EPA Response: This commenter supports the EPA's approach.

PFAS Project Lab (Doc. #1786, SBC-044715)

Moreover, EPA has undertaken toxicological evaluations of PFBS and HFPO-DA and it is thus critical that they also be included in current rulemaking given their adverse health outcomes. Communities are frequently exposed to these PFAS, as well as others, as mixtures in drinking water (Pelch et al. 2023) and scientific practice supports approaching the health risks posed by possible mixtures of PFHxS, HFPO-DA, PFNA, and PFBS as part of a Hazard Index. While EPA has adopted few MCLs in recent decades (and thus has not had much opportunity to employ this approach in drinking water regulation), Hazard Indices are commonly used by EPA, including in developing health protective clean-up goals under CERCLA.

EPA Response: This commenter supports the EPA's approach.

National Ground Water Association (NGWA) (Doc. #1804, SBC-045461)

Hazard Index (HI) · The "Mixture MCL" for PFNA, PFHxS, PFBS, and GenX makes technical sense, but may be confusing and esoteric to the public. Why would EPA not use an MCL consistent with the other contaminants? Use of the MCL is probably more easily understood by the public. Using the MCL for all contaminants clearly communicates whether a concentration is over or under the standard. NGWA recommends use of the MCL for all contaminants and not use of the Hazard Index.

EPA Response: Please see sections 4.3.2 and 1.2 of the EPA response in this *Response to Comments* document. After considering the comments, the EPA has established individual MCLGs and MCLs for three of these PFAS in addition to the Hazard Index MCLG and MCL. For the EPA's discussion on the establishment of stand-alone MCLs for PFHxS, HFPO-DA, and PFNA in addition to the Hazard Index MCL, please see section 5.2 of the EPA response in this *Response to Comments* document.

Earthjustice et al. (Doc. #1808, SBC-046106)

C. EPA's Proposed MCL for GenX, PFBS, PFNA and PFHxS is Consistent with the SDWA and Supported by the Record

i. A Hazard Index Is a Well Established and Appropriate Method of Addressing the Risks Posed by Mixtures of Multiple PFAS

For the HI PFAS, EPA proposed an MCLG and MCL using an approach that addresses the harms caused by each of those contaminants individually, as well as by their combined presence in drinking water supplies. This approach is well grounded in the SDWA, and it is needed to protect communities that have multiple PFAS in their drinking water supplies.

A hazard index is "commonly used" to measure and regulate risks from mixtures, or combinations, of contaminants that cause similar health effects. [FN79: Proposed Rule, 88 Fed. Reg. at 18,639.] Under this approach, EPA calculates each contaminant's "hazard quotient," or individual risk, by dividing the level of human exposure (i.e., the concentration of the contaminant in drinking water) by the level at which the contaminant presents risk to human

health (referring to be EPA as a Health-Based Water Concentration or "HBWC"). [FN80: Id.] A hazard quotient below 1 indicates an individual chemical is present below the level that is known to cause risk. To calculate the risk from the mixture, EPA adds the chemicals' hazard quotients to calculate a hazard index, with a hazard index above 1 generally indicating elevated risk to human health. [FN81: Id.] However, the use of a hazard index of 1 as an adequate health threshold relies on EPA's ability to address all of the harms associated with the chemicals at issue in their underlying toxicity assessments. Given the uncertainties inherent in the estimation of risk and the multitude of factors that are not included in EPA calculations– including the effects of non-chemical stressors and co-exposures to other PFAS that are not covered by the Proposed Rule – EPA should consider the use of a hazard index below 1 to provide the "adequate margin of safety" required by the SDWA. [FN82: 42 U.S.C. § 300g–1(b)(4)(A); see also Devon Payne-Sturges et al., Cumulative Risk Evaluation of Phthalates Under TSCA, 57 Env't Sci. & Tech. 6403, 6409 (2023), https://pubs.acs.org/doi/full/10.1021/acs.est.2c08364 (challenging the "traditional use of HI ≤ 1 as being 'safe' or acceptable for mixtures/multiple chemical exposures" and proposing "the use of a HI of 0.1–0.2 as a benchmark").]

Hazard indices have long been used by EPA offices and endorsed by leading scientific authorities, including EPA's Science Advisory Board. EPA calculates hazard indices under the Comprehensive Environmental Response, Compensation, and Liability Act to measure the cumulative effects of multiple contaminants at a Superfund site and to develop health-protective clean-up goals. [FN83: See EPA, EPA/540/1-89/002, Risk Assessment Guidance for Superfund: Volume I Human Health Evaluation Manual (Part A), Off. Of Emergency and Remedial Response, at 8-11–8-13, https://nepis.epa.gov/Exe/ZyPURL.cgi?Dockey=2000KLZ9.txt ("At most Superfund sites, one must assess potential health effects of more than one chemical … Estimating risk or hazard potential by considering one chemical at a time might significantly underestimate the risks associated with simultaneous exposures to several substances … To assess the overall potential for noncarcinogenic effects posed by more than one chemical, a hazard index (HI) approach has been developed based on EPA's (1986b) Guidelines for Health Risk Assessment of Chemical Mixtures.")] They are also used under the Clean Air Act to calculate chronic risks from multiple chemicals released by a given source category. [FN84: See National Emission Standards for Hazardous Air Pollutants: Cyanide Chemicals Manufacturing Residual Risk and Technology Review, 86 Fed. Reg. 3906, 3910-11 (Jan. 15, 2021).] Hazard indices address the potential for "low levels of multiple [chemicals] that individually would not likely result in adverse health effects . . .to result in adverse health effects" when combined in a mixture. This approach to calculating risk – also known as dose additivity – "has found widespread acceptance as an assessment concept for combined exposures to multiple chemicals . . . and is extensively used by regulatory authorities as a protective default approach." [FN85: Org. for Econ. Coop. and Dev., ENV/JM/MONO(2018)37, Considerations for Assessing the Risks of Combined Exposure to Multiple Chemicals: Series on Testing and Assessment No. 296, at 19 (Dec. 6, 2018), https://www.oecd.org/chemicalsafety/risk-assessment/considerations-for-assessing-the-risks-of-combined-exposure-to-multiple-chemicals.pdf.]

Here, a hazard index is necessary and appropriate to address the harms associated with the HI PFAS. As EPA found, "PFHxS, [GenX], PFNA, and PFBS … result[] in common adverse effects on several biological systems including thyroid hormone levels, lipid synthesis and metabolism, as well as on development, and immune and liver function." [FN86: Proposed Rule, 88 Fed. Reg. at 18,647.] Exposure to mixtures of those chemicals poses greater risks than exposure to each chemical in isolation, such that setting individual chemical MCLs would not fully protect people who have combinations of the HI PFAS in their drinking water. EPA also found, based on nationwide monitoring data, that "there is a substantial likelihood PFHxS, [GenX], PFNA, and PFBS will occur and co-occur with a frequency of public health concern." [FN87: Id.] "When three or four HI PFAS were monitored, over 40 percent of systems reported detections of two to three of the HI PFAS." [FN88: Id. At 18,676.] An MCL that ignores those co-exposures could leave millions of people at risk. [FN89: See id. At 18,678]

This is the precise scenario that has justified prior, mixture-based MCLs. In its disinfection byproducts rule, EPA set a combined MCL for five THMs that are detected together in drinking water and cause similar health effects. [FN90: 90 44 Fed. Reg. at 68,624, 68,626-28.] Because of their combined effects, regulating each component of that mixture in isolation would "permit a substantial number of communities . . . to avoid any improvement of treatment practice and, by implication, water quality." [FN91: Id. At 68,628.] As described above, EPA also regulated all PCBs under a single MCL because individual isomer limits would understate their combined risks. [FN92: 56 Fed. Reg. at 3,546.] Here, too, EPA cannot protect communities with multiple HI PFAS in their drinking water unless its MCL accounts for the harms associated with those chemicals' mixtures.

EPA Response: This commenter supports the EPA's approach. The agency agrees that it has the statutory authority to regulate mixture combinations containing some or all of these four PFAS. Please see section III.A.2 of the final rule preamble, as well as section 3.2 of the EPA response in this *Response to Comments* document regarding this statutory authority.

Earthjustice et al. (Doc. #1808, SBC-046107)

ii. EPA Should Maintain its Hazard Index Approach to Setting the MCLGs and MCLs for the HI PFAS While Updating its Hazard Index Calculations to Reflect the Best Available Science

With appropriate inputs, a hazard index of 1 reflects "the level at which no known or anticipated adverse effects on the health of persons occur" from exposure to the HI PFAS, as required for an MCLG. [FN93: 42 U.S.C. § 300g–1(b)(4).] Because the HI PFAS cause a range of harmful effects at different exposure levels, simply setting a maximum concentration for their combined presence in drinking water, as EPA has done for prior contaminant mixtures, would not address their "known or anticipated" adverse effects. [FN94: Id.] By dividing each contaminant's exposure level by the lowest level at which the contaminant is known to pose harm, EPA can calculate hazard quotients that are tailored to each contaminant and that protect against effects that occur at higher exposure levels. And by adding those quotients to calculate the hazard index,

EPA can protect against adverse effects from mixtures of the HI PFAS and ensure that people who are exposed to multiple HI PFAS are not placed at risk. [FN95: As described below, EPA should update its toxicity values (or Health Based Water Concentrations) for the HI PFAS to reflect the latest available science on those chemicals' hazards. Those revisions would not change the MCL or MCLG; they would merely ensure that the calculations that EPA used to calculate the hazard index are fully protective of human health.] However, this approach requires EPA to set HBWCs—the denominators in its hazard quotient equations [FN96: Proposed Rule, 88 Fed. Reg. at 18,665.] —at levels that protect against all of a contaminants' adverse health effects, including effects to "subgroups . . . such as infants, children, pregnant women, the elderly, individuals with a history of serious illness, or other subpopulations[] that are identifiable as being at greater risk of adverse health effects due to exposure to contaminants in drinking water than the general population." [FN97: 42 U.S.C. § 300g–1(b)(1)(C).] As explained below, EPA's proposed HBWCs do not address the HI PFAS' increased risks to infants and must be revised in a manner consistent with the best available science. We urge EPA to use the reduced HBWCs recommended below when calculating the Hazard Index for the purposes of setting the HI PFAS MCLG.

A hazard index of 1 is also "feasible with the use of the best [available] technology," and is a proper MCL. Here, as well, EPA should revise the denominators for its hazard index calculations. Because the HBWCs proposed below are significantly lower than the practical quantitation level for the HI PFAS, laboratories may not be able to detect MCL exceedances that are based on those levels. Therefore, when calculating the hazard index for the purpose of setting and implementing the MCL, we recommend that EPA use the PQL for each HI PFAS as the denominator, similar to EPA's approach for PFOA, PFOS, and other chemicals that pose health risks below their respective PQLs. This would ensure that the HI PFAS MCL is feasible, because (1) laboratories can already detect each HI PFAS down to the PQL and (2) water systems can reduce levels of the HI PFAS below their respective PQLs by using the same treatment technologies that EPA has proposed to address PFOA and PFOS, including granular activated carbon and reverse osmosis. [FN98: Proposed Rule, 88 Fed. Reg. at 18,665-66.] Similar to PFOA and PFOS, many communities are already using those technologies to treat water contaminated with GenX and other HI PFAS.

The SDWA does not dictate the form of an MCL or MCLG; it merely requires the MCLG to be set at a health-protective "level" and the MCL to be set as close as feasible to that level. EPA's Proposed Rule, with the changes recommended herein, satisfies those statutory requirements. In the past, EPA has set MCLs based on the percentage of water samples that detected a class of contaminants (total coliforms), as opposed to a density-based limit, because "the presence-absence concept is simpler and mathematically more precise than the current density standard for total coliforms[.]" [FN99: Drinking Water; National Primary Drinking Water Regulations; Total Coliforms (Including Fecal Coliforms and E. coli), 54 Fed. Reg. 27,544, 27,548 (June 29, 1989).] Similarly, a hazard index provides a "more precise" estimate of the HI PFAS' effects than a concentration-based limit, consistent with the SDWA's mandate to minimize those contaminants' adverse effects to the extent feasible.

EPA Response: This commenter supports the EPA's approach to use a Hazard Index MCLG. Please see section 4.3.3 of the EPA response in this *Response to Comments* document for the EPA responses to comments related to modifications of the HBWCs. At the final HBWCs, there are no analytical measurement limitations since the final HBWCs are all above each of the respective PFAS' PQLs. For additional discussion about the form of an MCLG/MCL, please see section 5.2.1 of the EPA response in this *Response to Comments* document.

Environmental Working Group et al. (Doc. #1810, SBC-044688)

The PFAS addressed by EPA's proposal are among a class of thousands of forever chemicals. EPA's proposal to use a hazard index to address multiple co-occurring PFAS recognizes the risks associated with harmful chemical mixtures. Like many members of the PFAS class, PFBS, PFNA, GenX, and PFHxS have similar chemical structures and cause similar health effects. Many communities are exposed to, and harmed by, mixtures of those PFAS in their drinking water. EPA's approach provides a framework for addressing additional PFAS and mixtures of chemicals in the future, which would allow the Agency to move more rapidly to protect public health.

EPA Response: This commenter supports the EPA's approach.

Little Hocking Water Association (Doc. #1835, SBC-045510)

Support of preliminary regulatory determinations for PFHxS, HFPO-DA, PFNA, and PFBS.

LHWA supports regulation and adoption of MCLs for the four proposed PFAS chemicals HFPO-DA, PFHxS, PFNA, and PFBS through the use of a Hazard Index of 1.0. Further, LHWA supports a MCLG of 1.0 as a Hazard Index.

EPA Response: This commenter supports the EPA's approach. Please also see section 4.3.4 of the EPA response in this *Response to Comments* document.

Citizens Energy Group (Doc. #1838, SBC-044854)

Section V – Maximum Contaminant Level Goal

EPA requests comment on the general HI approach for the mixture of four PFAS.

Citizens supports the proposed Hazard Index as an appropriate approach to manage risks associated with this complex class of chemicals. The use of the Hazard Index is similar to the way that the Clean Air Act programs regulate dioxin/furan emissions from stationary sources, allowing emission units to demonstrate compliance based on the combined toxicity of the compounds, weighted for relative toxicity, rather than numeric limits for individual compounds.

EPA Response: This commenter supports the EPA's approach.

Alliance of Nurses for Healthy Environments (Doc. #3072-27, SBC-047374)

Good afternoon. My name is Sarah Bucic and I have been a registered nurse for over 20 years and I am here with the Alliance of Nurses for Healthy Environments. We're the only national nursing organization focused solely on the intersection of health and the environment and we support EPA's proposed regulation of PFAS in drinking water under the Federal Safe Drinking Water Act. By establishing strong limits on six widely detected PFAS, the proposal would save thousands of lives and prevent tens of thousands of serious PFAS-related illnesses each year. National standards to limit the concentration of PFAS in drinking water are long overdue. EPA's proposal for the six PFAS would set the national standard for PFOA and PFOS at the lowest detection level approved by the Agency and would establish limits on GenX, PFBS, PFNA, and PFHxS using a hazard index. And because most people are exposed to mixtures of PFAS, EPA's proposal to use a hazard index to address multiple co-occurring PFAS recognizes the risks associated with harmful chemical mixtures.

EPA Response: This commenter supports the EPA's approach.

Massachusetts Water Resources Authority (Doc. #3072-49, SBC-047378)

Good afternoon and thank you. I'm Stephen Estes-Smargiassi, director of Planning and Sustainability at the Mass Water Resources Authority, today speaking for myself. I'll offer some very brief comments on key aspects of EPA's approach to this very important proposed regulation. National PFAS standard could reduce customer confusion associated with the very different state standards already in place. Unfortunately, components of this proposal failed to help with the confusion. The hazard index, most critically. Hazard index is typically used as a screening tool. It's relatively easy to calculate, but very difficult to explain to the typical lay audience we need to communicate with. Being able to communicate effectively about how we protect public health and how we determine what to invest in is key to public confidence.

EPA Response: Please see sections 4.3.2 and 1.2 of the EPA response in this *Response to Comments* document.

Alliance of Nurses for Healthy Environments (Doc. #1544, SBC-042666)

The PFAS class of chemicals includes over 12,000 different compounds with various chemical properties [FN4: National Academies of Sciences, Engineering, and Medicine (NASEM). (2022). Guidance on PFAS Exposure, Testing, and Clinical Follow-Up. Washington, DC: The National Academies Press. https://doi.org/10.17226/26156.] and most people are exposed to mixtures of PFAS such that specific effects are difficult to disentangle. However, the PFAS addressed by EPA's proposal are among this class of thousands of forever chemicals. EPA's proposal to use a hazard index to address multiple co-occurring PFAS recognizes the risks associated with harmful chemical mixtures. Like many members of the PFAS class, PFBS, PFNA, GenX, and PFHxS have similar chemical structures and cause similar health effects. Many communities are exposed

to, and harmed by, mixtures of those PFAS in their drinking water. EPA's approach provides a framework for addressing additional PFAS and mixtures of chemicals in the future, which would allow the Agency to move more rapidly to protect public health.

EPA Response: This commenter supports the EPA's approach.

Oregon Health Authority (OHA) (Doc. #1582, SBC-042757)

State of Oregon Comments on the Proposed PFAS Rule

Docket ID No. EPA-HQ-OW-2022-0114

Oregon Health Authority

May 25, 2023

XIV. Request for Comment on Proposed Rule: The Agency is requesting comment on this proposed National Primary Drinking Water Regulation (NPDWR) for PFAS. In the proposal, the Agency highlighted numerous areas where specific public comment will be helpful for EPA in developing a final rule. EPA specifically requests comment on the following topics within each section of this preamble.

As the state agency in Oregon with primacy for the Safe Drinking Water Act (SDWA), Oregon Health Authority (OHA) submits the following comments on the proposed NPDWR for PFAS for the following topics requested by EPA.

Section V – Maximum Contaminant Level Goal

• EPA requests comment on the general Hazard Index (HI) approach for the mixture of four PFAS.

OHA applauds the EPA for pursuing a class approach to four out of the six PFAS species proposed for regulation under the Safe Drinking Water Act. The HI approach acknowledges evidence suggesting that many PFAS species have similar biological targets and cumulatively affect toxicity in an additive fashion. While the proposed Health-Based Water Concentrations (HBWCs) for the four PFAS included in the HI approach are not all based on the same critical health effect, the proposed approach provides optimal public health protection in the face of scientific uncertainty

• EPA requests comment on the merits and drawbacks of the target-specific HI or relative potency factor (RPF) approach.

The merits of a target-specific HI or RPF approach include greater certainty about the additive nature of the cumulative impact of exposure to all four of these PFAS species. The main drawback is that the approach could result in residual risk if any of the included PFAS species have critical health effects at doses lower than the shared effects upon which their common-target HBWCs would be based. To protect against this, a target-specific HI approach would

require additional consideration of that residual risk on an individual PFAS species basis. That would add complexity to the process that is probably not warranted.

Therefore, OHA favors the simple HI approach proposed by EPA as there are no concerns about residual risk of critical effects for specific PFAS outside any shared target-organ effects. OHA encourages EPA to stick with the simple HI approach for the four included PFAS as proposed.

EPA Response: This commenter supports the EPA's approach. The EPA agrees that the TOSHI and RPF approaches would underestimate risk, and thus would not be consistent with the statutory definition of MCLG. Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Suffolk County Water Authority (SCWA) (Doc. #1589, SBC-043366)

3. Use of a Health Index for MCLs or MCLGs Will be Complicated and Confusing

While the use of a health index for determining dose additive health effects for selected PFAS may have merit from a technical perspective, utilizing a health index for a combined MCLG or MCL will be complicated and confusing for public water suppliers and their customers. A health index will add complexity for water systems trying to determine whether or not they have violated or are approaching an MCL at a particular location. Similarly, reporting PFAS health index analyses in a Consumer Confidence Report will likely not add to a consumer's confidence but only create consumer confusion.

For operational simplicity and customer communication purposes, contaminant specific MCLs and MCLGs would be preferred for the four PFAS for which EPA is considering a health index. However, if EPA wanted to maintain the PFAS health index as the MCLG, one alternative would be to set the MCLs for the four PFAS in the index at their respective health based water concentrations (HBWC). Thus, the MCLG would utilize the health index, but the enforceable MCL would be set at the respective HBWCs. Such a change would eliminate the vast majority of the complexity and confusion issues regarding a health index.

EPA Response: Please see sections 4.3.2 and 1.2 of the EPA response in this *Response to Comments* document. After considering the comments, the EPA has established individual MCLGs and MCLs for three of these PFAS in addition to the Hazard Index MCLG and MCL. For the EPA's discussion on the establishment of stand-alone MCLs for PFHxS, HFPO-DA, and PFNA in addition to the Hazard Index MCL, please see section 5.2 of the EPA response in this *Response to Comments* document.

Consumer Reports (Doc. #1656, SBC-043190)

For PFHxS, GenX chemicals, PFNA, and PFBS, and their mixtures, EPA has decided to use the Hazard Index (HI) methodology, which EPA regularly uses, for example in the Superfund program, to understand the health risks from chemical mixtures as the basis for setting a MCLG.

The HI approach assumes there is a dose additivity to the different chemicals in a mixture. This assumption of dose additivity is particularly clear in cases where each of the chemicals has a common mechanism of action and mainly affect the same human health endpoint. EPA considered two main types of HI approaches: 1) general HI which allows for each chemical in the mixture to have different health endpoints as the basis for the component chemical health-based reference value (e.g., RfD, HBWC) and 2) target-organ specific HI which relies on reference values based on the same organ or organ system (e.g., liver-, thyroid-, or developmental-specific).

The general HI is based on the overall RfD which is protective of all the effects for a given chemical regardless of organ or organ system, and thus a more protective estimate of risk, while the target-organ specific HI is a less protective estimate of risk since it focuses on only one target organ. For example, if a chemical has effects on multiple organs, the one target organ chosen for the HI may be one for which the effect may be less potent than on another organ or for which there may be significant currently unquantified effects due to lack of data. In addition, many PFAS lack human epidemiological or experimental animal hazard and dose-response data across a broad effect range which would limit determining target-organ specific values. EPA also considered the relative potency factor (RPF) approach, which represents the relative difference in potency of an effect/endpoint between a specific chemical and other chemicals in the mixture. The RPF approach has the same limitations as the organ-specific HI. EPA proposes to use the general HI as the most appropriate approach for considering PFAS mixtures, because the four PFAS chemicals frequently co-occur and can be expected to adversely impact multiple (but in many cases shared) health endpoints.

We agree with EPA that the general HI is the most appropriate approach for setting a MCLG for mixtures of PFHxS, GenX chemicals, PFNA, and PFBS since this approach adds an appropriate margin of safety for a class of contaminants that have been shown to co-occur in mixtures and for which there may be dose additivity since they share similar profiles of health effect areas (e.g., liver, thyroid, developmental, cardiovascular, etc.). Neither the target-organ HI approach nor the RPF approach will add an appropriate margin of safety.

The general HI is defined as the sum of the Hazard Quotient (HQ) for each chemical in a mixture. HQs are the ratio of potential exposure to a chemical and the level at which no health effects are expected. The HQ for a specific chemical is the exposure level (defined as its concentration in the drinking water) divided by the health reference value, in this case the HBWC (health-based water concentration) for that chemical. The MCLG for a mixture of PFHxS, GenX chemicals, PFNA, and PFBS is set at 1.

As noted previously, the HBWCs for PFHxS, GenX chemicals, PFNA, and PFBS are 9 ppt, 10 ppt, 10 ppt, and 2,000 ppt, respectively. Note that if the level of a specific chemical in drinking water exceeds the HBWC, then the HQ would be > 1, e.g., that specific chemical would exceed the “safe” level . Using the general HI approach, the levels of each chemical can be below their “safe” level (the HBWC), e.g., their HQ < 1, yet the HI could exceed 1 and so the mixture could be considered unsafe. For example, let’s say that levels of PFHxS, GenX chemicals, PFNA, and

PFBS in a drinking water sample are all 5 ppt, e.g., below the HBWC for each PFAS. The HI = (5 ppt/9 ppt) + (5 ppt/10 ppt) + (5 ppt/10 ppt) + (5 ppt/2,000 ppt) = .55 + .5 + .5 + .025 = 1.58. This shows the additive effect of the HI.

We agree with EPA that the MCLG for the mixture of PFHxS, GenX chemicals, PFNA, and PFBS should be the same as the HI and set at 1.

EPA Response: This commenter supports the EPA's approach.

Maine Organic Farmers and Gardeners Association (MOFGA) (Doc. #1660, SBC-043382)

We agree with EPA that the rule shouldn't be limited to PFOA and PFOS, and we support the hazard index approach for the other PFAS. While PFOA and PFOS continue to contaminate water and soil even 30 years after sludge was spread, newer chemicals including GenX are also ubiquitous and pose health hazards. For example, a recent study in 16 states (including Maine) detected 26 unique PFAS in water samples, including 12 not covered by current EPA testing methods. [FN4: Science in the Total Environment, https://www.sciencedirect.com/science/article/pii/S0048969723015966?via%3Dihub#bb0115]

EPA Response: This commenter supports the EPA's approach.

Citizens Energy Group (Doc. #1838, SBC-044859)

EPA requests comment on its proposal of using an HI approach for PFHxS, HFPO-DA, PFNA, and PFBS, including whether it can be clearly implemented and achieves the goal of protecting against dose additive noncancer health effects.

Citizens believes that it is appropriate to use the proposed Hazard Index (HI) for the group of four PFAS compounds and that the HI approach can be implemented by water systems. The proposed HI is parallel to approaches used in other media (dioxins/furans in air, for example), to acknowledge differences in toxic endpoints in a broad class of contaminants that may be present in mixtures.

EPA Response: This commenter supports the EPA's approach.

North Carolina Division of Water Resources (NCDEQ) (Doc. #1652, SBC-044169)

A. General Comments

1. NCDEQ supports EPA's efforts to collectively address PFAS as a group in a regulatory framework in addition to multiple individual maximum contaminant levels (MCLs).

NCDEQ supports EPA's decision to develop an NPDWR that addresses PFAS as a group in addition to MCLs for individual substances. PFAS are rarely found in the environment as a single chemical and the general public is demanding that cumulative health effects of multiple PFAS chemicals be considered. EPA's proposed standard method that accounts for health risks

associated with a group of PFAS based on available scientific data is a necessary first step for the long-term management of this class of chemicals.

EPA Response: This commenter supports the EPA's approach.

Horsham Water & Sewer Authority (HWSA) (Doc. #1686, SBC-043818)

While we stated earlier that we would not comment on the proposed PFOA and PFOS MCLs, we do wish to address the proposed Hazard Index (HI) MCL for the combination of PFBS, PFNA, PFHxS and GenX. We believe this HI is unnecessarily complicated and not appropriate. If EPA has occurrence data and health data that supports a regulatory determination for each of these compounds, then make that determination and move forward with individual MCLs.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. After considering the comments, the EPA has established individual MCLGs and MCLs for three of these PFAS in addition to the Hazard Index MCLG and MCL. For the EPA's discussion on the establishment of stand-alone MCLs for PFHxS, HFPO-DA, and PFNA in addition to the Hazard Index MCL, please see section 5 of the EPA response in this *Response to Comments* document.

Clean Water Action/Clean Water Fund (Doc. #1697, SBC-045002)

The Hazard Index Proposal for Four PFAS

Although a hazard index approach has not been used in drinking water regulation, the concept of reducing public health risk from groups of chemicals is not new. Several NPDWRs address groups of contaminants, including regulations around disinfection byproducts and radionuclides. The concept of regulating drinking water contaminants as a class, rather than setting individual limits for every contaminant in the group or class, is also not a new one. One of the principles in EPA's 2010 Drinking Water Strategy was to "Address contaminants as a group rather than one at a time so that enhancement of drinking water protection can be achieved cost-effectively."[FN5: EPA Administrator Jackson Outlines New Vision for Clean, Safe Drinking Water, EPA press release, March 22, 2010] EPA's Science Advisory Board noted that it is "a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media."[FN6: Review of EPA's Analyses to Support EPA's National Primary Drinking Water Rulemaking for PFAS, EPA Science Advisory Board, August 22, 2022, p.91]

The Hazard Index approach, also addresses the dose additive impacts of exposure to multiple PFAS chemicals at low levels in a way that individual contaminant limits would not. Exposure to mixtures of PFAS chemicals can have health impacts that exposure to the individual chemicals at those low levels would not. This is a critical issue and Hazard Index approach allows for consideration of this dose additive characteristic of exposure to groups of PFAS chemicals at low levels. As noted in the proposal, the Hazard Index approach also allows for the addition of more

PFAS chemicals as information becomes available to develop the Health Based Water Concentration and to assess occurrence.

EPA Response: This commenter supports the EPA's approach.

Citizens Campaign for the Environment (CCE) (Doc. #1710, SBC-045134)

• Adopt EPA's Proposed Hazard Index of one unitless for four additional PFAS

CCE supports EPA's proposed Hazard Index of unitless one for perfluorononanoic acid (PFNA), hexafluoropropylene oxide dimer acid (HFPO-DA, commonly known as GenX Chemicals), perfluorohexane sulfonic acid (PFHxS), and perfluorobutane sulfonic acid (PFBS). This is a critical step to better protecting the public from the suite of PFAS chemicals that may be present in drinking water. Exposure to multiple PFAS chemicals simultaneously has the potential to worsen health impacts. There is growing concern and scientific evidence on the combined synergistic effect exposure to multiple PFAS chemicals can have. A recent study evaluating the combined toxicological effects of PFOS, PFOA, PFNA, PFDA, PFHxS, and PFHpA on liver cells found that overall, the toxicological interactions of these PFAS chemicals had a synergistic effect especially at low to medium levels. [FN2: Combined Effect and Toxicological Interactions of Perfluoroalkyl and Polyfluoroalkyl Substance mixtures in Human Liver Cells. Atinuke F. Ojo, Cheng Peng, Jack C. Ng, 2020. https://www.sciencedirect.com/science/article/abs/pii/S0269749119361469?via%3Dihub] Given the potential for synergistic effects of PFAS chemicals, it is crucial that the EPA adopt this strong Hazard Index standard.

EPA Response: This commenter supports the EPA's approach.

West Virginia Rivers Coalition et al. (Doc. #1746, SBC-045247)

Taken together, PFHxS, HFPO-DA, PFNA, and PFBS occur and co-occur in both raw-water and finished water of PWSs in West Virginia with a frequency and at levels of public health concern. We support EPA's proposal of a hazard index (HI) to address the harms caused by each of these contaminants individually, as well as by their combined presence in drinking water. The use of such an index is most protective of public health, and needed to protect our communities exposed to multiple PFAS in their drinking water.

EPA Response: This commenter supports the EPA's approach.

Center for Environmental Health et al. (Doc. #1764, SBC-044243)

We agree with EPA's Hazard Index (HI) Approach to calculating MCLs for PFBS, PFHxS, PFNA, HFPO-DA and its ammonium salts. The hazard index, (HI) defined in the proposal as

[Equation 1: see docket ID EPA-HQ-OQ-2022-0114-1764]

where the Hazard Quotient, HQ is the ratio of the PFAS occurrence concentration, E, in mg/L and the reference value, RfV, is consistent with the prevailing scientific view that the health risks of these four PFAS are additive in mixtures, and therefore the presence of any one in a mixture could present significant health risks in drinking water. In the absence of best available scientific data EPA should continue exercising precautions to protect the most vulnerable populations while also requiring responsible parties, like the chemical industry, to fully fund independent human epidemiological studies on already overexposed populations.

We support the MCLs of the proposed NPDWS as calculated using the HI approach and urge EPA to quickly finalize them. We further urge EPA to continue updating its HI calculations by sourcing data collected using its authority under Section 4 of TSCA in addition to calculating RfVi from publicly available UCMR3 and State-level water data in the issuance of future drinking water standards.

EPA Response: This commenter supports the EPA's approach.

Environmental Protection Network (EPN) (Doc. #1773, SBC-043853)

Hazard Index MCLG

EPN commends EPA for using a general Hazard Index (HI) approach to address the additive effects of four co-occurring PFAS chemicals. We note that this approach has been used for years by EPA and the states under the Superfund program and is well-suited to address the thousands of PFAS chemicals in the environment. We believe that the general HI provides a framework for all future PFAS drinking water standards because additional compounds can be included as more information becomes available on their health effects, exposures, analytical methods, and treatment efficiency.

Due to widespread use and persistence, many PFAS compounds are known to co-occur in drinking water and the environment, often found in different combinations as mixtures. All the PFAS chemicals studied to date have been found to cause common adverse effects on several biological systems and functions, including thyroid hormone levels, lipid synthesis and metabolism, fetal and infant development, immune and liver function. The general HI allows for component chemicals to have different health effects or endpoints as the basis for their chemical reference values. A target-organ specific HI is less health protective when contaminants like PFAS impact multiple organs, and the target-organ is not the most sensitive endpoint for all the component chemicals.

EPA Response: This commenter supports the EPA's approach.

Minnesota Pollution Control Agency (MPCA) (Doc. #1569, SBC-042490)

Section V - Maximum Contaminant Level Goal (MCLG)

1) EPA requests comment on the general HI approach for the mixture of four PFAS.

MPCA response:

• MPCA supports the use of a general HI approach for the mixture of four PFAS given that there are limitations to deriving health effect-specific reference doses for many PFAS.

EPA Response: The commenter supports the EPA's approach.

New England Interstate Water Pollution Control Commission (NEIWPCC) (Doc. #1650, SBC-043151)

Hazard Index Approach

Generally, our member states are supportive of the proposed Hazard Index approach, albeit with an important caveat. Our member states note that the flexibility inherit with this approach allows for easier modifications in the future. Such modifications could include the refinement of the MCLs, the future addition of other compounds, and the removal of a compound for stand-alone regulation. We generally also prefer the Hazard Index approach over the summing approach some states are currently utilizing. Overall, we find that the Hazard Index approach more effectively considers the variation in MCLs across all PFAS compounds.

EPA Response: The commenter supports the EPA's approach.

Consumer Reports (Doc. #1656, SBC-043192)

The MCL for the mixtures of PFHxS, GenX chemicals, PFNA, and PFBS would be an HI = 1.0. The EPA has also determined that there are validated analytical methods (EPA Method 533 and 537.1) that can measure below the HBWC for each of these PFAS. EPA has determined that multiple technologies (i.e., GAC, AIX, RO and NF) are both available and have demonstrated PFAS removal efficiencies that may exceed >99 percent and that achieve concentrations below their PQLs (between 3.0–5.0 ppt) at a reasonable cost based on large and metropolitan water systems.

We support EPA's proposal to set the HI for the mixtures of PFHxS, GenX chemicals, PFNA, and PFBS at an HI = 1.0, since it is feasible to test drinking water at that level and multiple treatment technologies exist to reduce PFHxS, GenX chemicals, PFNA, and PFBS to below their specific HBWC at reasonable cost.

Best,

Michael Hansen, Ph.D.

Senior Scientist

EPA Response: The commenter supports the EPA's approach. Please also see section 4.3.4 of the EPA response in this *Response to Comments* document.

Greater North Dakota Chamber et al. (Doc. #1593, SBC-042802)

The novel hazard index approach. The hazard index approach for the PFAS other than PFOA and PFOS has never been used in setting an MCL, and it presents technical, scientific, and legal questions about how it would be implemented.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. For the EPA response to comments about technical, scientific, and legal questions related to an MCL based on the Hazard Index approach, please see section 5 of the EPA response in this *Response to Comments* document.

Pennsylvania Department of Environmental Protection (Doc. #1626, SBC-044883)

Proposed Hazard Index (HI) MCL

• DEP supports EPA's efforts to set a group MCL for PFAS. However, we do not believe that the use of a proposed HI is appropriate or feasible.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Pennsylvania Department of Environmental Protection (Doc. #1626, SBC-052942)

• DEP has concerns regarding the use of the HI as a drinking water MCL as it is proposed. It is DEP's understanding that the HI is typically used as site-specific cleanup criteria, where the full range of contaminants likely to be present at a contamination site is known. Those contaminants, specific to an individual site, can be evaluated for overall risk based on several factors, including how they interact with one another, exposure factors, toxicity values, etc. By attempting to apply the HI concept as an across-the-board drinking water standard, it becomes an arbitrary evaluation of just those four contaminants included in the calculation. Any other contaminants that may be

present and may interact with the four HI PFAS are not accounted for. It is important to note that when used appropriately as cleanup criteria at a specific site, the HI would take into account not just other PFAS, but also any other type of interacting contaminant that may contribute to overall risk. As proposed, this HI MCL arbitrarily considers only the four HI PFAS, which DEP believes is not an appropriate application of the HI concept.

EPA Response: While it is recognized that any given site or exposure medium (e.g., water) may include a diverse landscape of environmental chemicals, in addition to PFAS, the expressed focus of the current NPDWR is on the PFAS indicated (i.e., HFPO-DA, PFBS, PFHxS, PFNA). Also, although component-based mixtures methods such as the Hazard Index have predominately been applied under site-specific assessment contexts (e.g., CERCLA), there is no indication in any existent EPA guidance that precludes application to other problem formulations under other authorities (e.g., SDWA). Additionally, the EPA disagrees that the Hazard Index MCL arbitrarily considers only the four PFAS because under the SDWA regulatory determination process, the EPA is required to evaluate contaminants using the three statutory criteria. As described within section III of the final rule preamble and in section 3 of this *Response to Comments* document, the agency has completed this evaluation and there is available health, occurrence, and other meaningful opportunity information for three PFAS (PFHxS, PFNA, and HFPO-DA) to meet the SDWA statutory criteria for regulation individually and four PFAS (PFHxS, PFNA, HFPO-DA, and PFBS) as a mixture. In addition, the commenter hasn't explained why the Hazard Index approach is not appropriate for regulation of a mixture under SDWA.

Pennsylvania Department of Environmental Protection (Doc. #1626, SBC-052943)

• DEP also notes that the HI calculation included in the proposed rulemaking is a shortcut method to estimate HI that does not allow for an actual risk calculation. The proposed HI calculation uses HQs that are determined by comparing the measured concentration of a contaminant to the HBWC. As noted above, this calculation does not include values such as exposure factors and toxicity values that are typically included in HI determinations. Without that additional information, it is not possible to fully quantify the risk level with the HI. Therefore, it is not appropriate to introduce an HI MCL as a drinking water standard.

EPA Response: The EPA disagrees with this comment. The Hazard Index is not a "shortcut method … that does not allow for an actual risk calculation." On the contrary, the Hazard Index is a component-based mixture assessment approach that provides an indication of risk (USEPA, 1986; USEPA, 1991c, USEPA, 2000b; USEPA, 2023j). A Hazard Index greater than 1 (rounded to one significant digit) indicates that exposure from the combination of PFAS (i.e., in drinking water) exceeds the health-protective level (based on dose additivity), and thus, risk is indicated. A Hazard Index less than or equal to 1 indicates that occurrence of these four PFAS in drinking water does not exceed the health-protective level and is therefore generally regarded as unlikely to result in any appreciable risk (USEPA, 1986; USEPA, 1991c; USEPA, 2000b). In this application in the NPDWR, the Hazard Index does include exposure factors and

toxicity reference values to derive the HBWCs, which are subsequently used to calculate the Hazard Index (for a complete description of HBWC inputs, please see USEPA, 2024h). See also section 4.3.2 of the EPA response in this *Response to Comments* document.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052849)

It is also indefensible to base a regulatory standard with broad applicability to 66,000 water systems and numerous contaminated sites across the country on a risk assessment tool developed for case-by-case application to ensure appropriate decision-making. [FN14: See, e.g., USEPA, Guidelines for the Health Risk Assessment of Chemical Mixtures, EPA/630/R-98/002 at vii (September 1986) (hereinafter, "Mixtures Guidelines") ("In particular, the guidelines emphasize that risk assessments will be conducted on a case-by-case basis, giving full consideration to all relevant scientific information. This case-by-case approach means that Agency experts review the scientific Information on each agent and use the most scientifically appropriate interpretation to assess risk."] Similarly, it is inappropriate to base a regulatory standard on the use of a tool that EPA guidance recommends only for screening. And further, the Proposal uses the HI approach in a manner contrary to EPA's guidance by seeking to add impacts based on different health effect end points based on only animal studies. [FN15: See, e.g., USEPA, Guidance for Identifying Pesticide Chemicals and Other Substances That Have A Common Mechanism of Toxicity (January 29, 1999).] While the preamble asserts that the health effects of these substances are additive, [FN16: See, e.g., 88 Fed. Reg. 18639 (exposure to a mixture of PFAS in drinking water "can be assumed" to act in a dose-additive manner); 88 Fed. Reg. 18645 (mixtures "are anticipated" to affect common organs, tissues and systems to produce dose-additive effects); 88 Fed. Reg. 18650 (PFAS "are likely" dose additive).] the proffered health effect endpoints on which EPA bases its HBWC differ – body weight gain and developmental delays in mice for PFNA, thyroid effects in male rats for PFHxS, thyroid effects in mice for PFBS and liver lesions in female mice for GenX. EPA admits that there is no consensus on whether or how PFAS should be combined for risk assessment purposes. [FN17: 88 Fed. Reg. 18654.] In addition, EPA is further adding more specificity to what should be a screening tool by setting the HI using two significant digits, contrary to EPA's guidance and longstanding practice as well as basic mathematical rounding rules.

EPA Response: The EPA disagrees with these comments. Please see sections 4.3, 4.3.2, and 4.3.4 of the EPA response in this *Response to Comments* document. Additionally, the EPA disagrees that "It is also indefensible to base a regulatory standard with broad applicability to 66,000 water systems and numerous contaminated sites across the country on a risk assessment tool developed for case-by-case application to ensure appropriate decision-making." The commenter is incorrect stating that it is "indefensible" to set an MCLG using the Hazard Index approach. In fact, given the temporal and spatial variability of PFAS occurrence in drinking water across the nation (USEPA, 2024j), it is not merely defensible, but appropriate to regulate these chemicals in drinking water by taking a flexible approach that considers site-specific data at each PWS. Component PFAS HQs are expected to differ across time and space depending on

the actual measured concentrations of each of the four PFAS. This approach allows for flexibility beyond a one-size-fits-all approach and is tailored to address risk from mixtures of these PFAS at each PWS. Furthermore, consistent with the statutory standard in SDWA, use of the Hazard Index ensures that the EPA sets an MCLG for mixtures of two or more of PFNA, PFHxS, HFPO-DA, and PFBS at a level at which there are no known or anticipated health effects on the health of persons, and allowing an adequate margin of safety.

The EPA acknowledges that there remains a lack of "consensus on whether or how PFAS should be combined for risk assessment purposes." Under the statute, the EPA must act based on the "best available" science and information. Thus, the statute recognizes that the EPA may act in the face of imperfect information. It also provides a mechanism for the EPA to update standards as more science becomes available. For the PFAS covered by this rule, the EPA concluded that the state of the science and information has sufficiently advanced to the point to satisfy the statutory requirements and fulfill SDWA's purpose to protect public health by addressing contaminants in the nation's PWSs.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052850)

The HI approach should not remain in the final rulemaking. EPA guidance is clear on the point that the HI approach is a rough measure that should be used only as a screening tool. [FN18: EPA's use of the HI approach in connection with the Clean Air Act is similarly as a screening tool. See EPA, AirToxScreen Overview, available at https://www.epa.gov/AirToxScreen/airtoxscreen-overview.]

• "The hazard index provides a rough measure of likely toxicity and requires cautious interpretation." [FN19: Mixtures Guidelines at 9.]

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Also, the EPA acknowledges that the quoted statement is in Appendix A of its supplemental mixtures guidance (USEPA, 2000b); however, the guidance goes on to say the following (emphasis added):

"The hazard index is only a numerical indication of the nearness to acceptable limits of exposure or the degree to which acceptable exposure levels are exceeded. As this index approaches unity, concern for the potential hazard of the mixture increases. If the index exceeds unity, the concern is the same as if an individual chemical exposure exceeded its acceptable level by the same proportion."

This means that if the HI approaches 1 the potential hazard associated with the mixture increases, and when it is above 1, risk is indicated in the same way that it would be if an individual chemical exposure exceeded its acceptable level by the same proportion. An HI greater than 1 is generally regarded as an indicator of adverse health risks associated with a specific level of exposure to the mixture; an HI less than or equal to 1 is generally regarded as not being

associated with any appreciable risk (USEPA, 1986; USEPA, 1991c; USEPA, 2000b). Thus, in the case of this drinking water rule, an HI greater than 1 indicates that occurrence of two or more of the four component PFAS in a mixture in drinking water exceeds the health protective level(s) (i.e., HBWC(s)), indicating health risks. The EPA maintains that the HI MCLG is consistent with EPA chemical mixtures guidance (USEPA, 2000b) as well as the EPA's obligation under SDWA (Section 1412(b)(4)(A)) to set MCLGs at "the level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety." The EPA acknowledges that its AirToxScreen is a nonregulatory tool to provide communities with information about health risks from air toxics.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052851)

• "[T]he act of combining all compounds, even if they induce dissimilar effects, is a screening procedure and not the preferred procedure in developing a hazard index." [FN20: Mixtures Guidelines at 26.]

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052852)

• "When used with components of unknown or dissimilar action, the hazard index is less accurate and should be interpreted only as a rough indication of concern." [FN21: Mixtures Guidelines at 27.]

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. The EPA's chemical mixtures guidance (USEPA, 2000b) articulates that an ideal condition for evaluation of dose additivity of component chemicals is at the level of common mode of action (MOA; also referred to as 'toxic action'). However, the guidance also says that the dose additivity assumption can be relaxed to the level of toxicological similarity (i.e., same/similar adverse health effect) in order to use component-based mixture assessment methods such as the Hazard Index. This is captured in the Hazard Index section of the 2000 EPA chemical mixtures guidance as follows: "In practice, because of the common lack of information on mode of action and pharmacokinetics, the requirement of toxicologic similarity is usually relaxed to that of similarity of target organs" (USEPA, 2000b). This approach (i.e., relying on common health domains), was supported by the EPA Science Advisory Board review of the draft PFAS Mixtures Framework (USEPA, 2022b). Furthermore, the commenter pulled the quote from a response to public comments found in part B of Appendix A of the EPA supplemental mixtures guidance; this same text is not found or communicated in the body of that document.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052853)

EPA guidance is also clear on the point that use of the HI approach for anything other than screening should be based on a single health outcome:

• "Dose additivity is based on the assumption that the components in the mixture have the same mode of action and elicit the same effects." [FN22: Mixtures Guidelines at 14.]

• "The biological basis for dose addition is the similarity of chemical components regarding toxicologic behavior, such as toxic mechanism, mode of action, or endpoint." [FN23: USEPA, Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures, EPA/630/R-00/002 at 80 (August 2000) (hereinafter "Supplementary Mixture Guidance").]

• "[D]ose additive models are not the most biologically plausible approach if the compounds do not have the same mode of toxicologic action." [FN24: Mixtures Guidelines at 8.]

EPA Response: Please see section 4.3.1 of the EPA response in this *Response to Comments* document. The EPA supplemental mixtures guidance (USEPA, 2000b) does indeed articulate that an ideal condition for evaluation of dose additivity of mixture component chemicals is at the level of common MOA (also referred to as 'toxic action'). However, the guidance document also posits that dose additivity interpretation can be relaxed to the level of toxicological similarity (sans MOA) and applied in component-based mixture assessment methods such as the Hazard Index. This is captured in the Hazard Index section (section 4.2) of the 2000 EPA supplemental mixtures guidance as follows: "In practice, because of the common lack of information on MOA and pharmacokinetics, the requirement of toxicologic similarity is usually relaxed to that of similarity of target organs." This approach (i.e., relying on common health domains) was supported by the EPA Science Advisory Board review of the draft PFAS Mixtures Framework (USEPA, 2022b).

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052854)

• "[T]he Hazard Index is then usually developed for each exposure route of interest, and for a single specific toxic effect or for toxicity to a single target organ." [FN25: Supplementary Mixture Guidance at 79.]

• "One of the key desirable features is the constraint to use only data on the effect of concern. Because the Hazard Index is tied to a specific effect, the underlying data should be on that effect." [FN26: Supplementary Mixture Guidance at 85.]

• "A separate HI should be calculated for each toxic effect of concern." [FN27: Supplementary Mixture Guidance at 86.]

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. Also, the EPA supplemental mixtures guidance (USEPA, 2000b) also states:

"The default procedure for the HI has traditionally been to use the RfD or RfC (U.S. EPA, 1989a). Because of their much wider availability than TTDs, standardized development process including peer review, and official stature, the RfD and RfC are recommended for use in the default procedure for the HI." Further, the EPA's Risk Assessment Guidance for Superfund (RAGS) Volume I Human Health Evaluation Manual (Part A) states on pg. 8-15 "Segregation of hazard indices requires identification of the major effects of each chemical including those seen at higher doses than the critical effect (e.g., the chemical may cause liver damage at a dose of 100 mg/kg-day and neurotoxicity at a dose of 250 mg/kg-day). Major effect categories include neurotoxicity, developmental toxicity, reproductive toxicity, immunotoxicity, and adverse effects by target organ (i.e., hepatic, renal, respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, and dermal/ocular effects). *Although higher exposure levels may be required to produce adverse health effects other than the critical effect, the RfD can be used as the toxicity value for each effect category as a conservative and simplifying step*." (italics added for emphasis).

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052855)

In summary,

[A] limitation with the hazard index approach is that the assumption of dose additivity is most properly applied to compounds that induce the same effect by the same mechanism of action. Consequently, application of the hazard index equation to a number of compounds that are not expected to induce the same type of effects or that do not act by the same mechanism could overestimate the potential for effects, although such an approach is appropriate at a screening level. [FN28: USEPA, Risk Assessment Guidance for Superfund, Volume I, Human Health Evaluation Manual (Part A), EPA/540/1-89/002 at 8-14 (December 1989).]

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052856)

This conclusion is consistent with the conclusions of the SAB. While EPA relies on the review of the SAB to justify its use of an HI, EPA's reliance is misguided and inconsistent with the SAB input. [FN29: See, e.g., 88 Fed. Reg. 18639, 18654 (quoting SAB Report but ignoring immediate prior sentences identifying HI as a screening level approach and indicating that toxicological studies to inform human health risk assessment are lacking for most PFAS and mixtures of PFAS).] Importantly, the SAB did not review the HI approach in connection with it being an

MCL and MCLG. Rather, SAB concluded the HI approach is appropriate as a screening tool, as EPA's guidance also concludes. Specifically, SAB stated:

In general, the screening level Hazard Index (HI) approach, in which Reference Values (RfVs) for the mixture components are used regardless of the effect on which the RfVs are based, is appropriate for initial screening of whether exposure to a mixture of PFAS poses a potential risk that should be further evaluated. [FN30: USEPA, Science Advisory Board, Review of EPA's Analyses to Support EP''s National Primary Drinking Water Rulemaking for PFAS, FINAL REPORT (hereinafter "SAB Review Report") at 91 (August 22, 2022); see also 88 Fed. Reg. 18655 ""the SAB emphasized that using a HI in the context of developing regulations for PFAS should not be directly interpreted as a quantitative estimate of mixture risk. Rather the SAB agreed that the HI can be used as an indicator of potential health risk(s) associated with exposure to mixtures of PFAS""")]

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052857)

In fact, regardless of how it, and SAB's review of it, was painted in the preamble to the Proposed Rule, [FN31: See, e.g., 88 Fed. Reg. 18662] EPA's Framework for Estimated Noncancer Health Risks Associated with Mixtures of Per- and Polyfluoroalkyl Substance (PFAS) comes to the same conclusion, recognizing the differences and weaknesses of a screening-level HI versus a target-organ-specific HI. [FN32: See USEPA, Framework for Estimated Noncancer Health Risks Associated with Mixtures of Per-and Polyfluoroalkyl Substance (PFAS), EPA 822D-21-003 (November 2021) (hereinafter, "Framework").] The Framework highlights that the HI is only "an indication of potential hazard, not an estimate of the concentration of the mixture in water that may result in adverse health outcomes after a specific period of exposure" and that "[c]omparisons of HI estimates across different exposure scenarios can be misleading." [FN33: Framework at 41. Note that PFOA and PFOS might also be used as indicators of the same risk(s) posed by at least three of the four PFAS included in the HI approach, making the HI approach superfluous and unnecessary.]

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-052858)

Further undermining the appropriateness of the HI approach is the lack of human toxicity data and the corresponding high uncertainty factors used to develop the HWBC, calling into serious question whether, even if a blended MCLG and MCL were appropriate, it would satisfy the SDWA's requirement to use the best available, peer-reviewed science. [FN34: See 42 U.S.C. §

300g-1(b)(3)(A).] EPA's reference dose for PFNA, GenX chemicals, PFHxS, and PFBS is based entirely on laboratory animal studies, even though EPA itself advises "[a]dequate human data are the most relevant for assessing risks to humans" [FN35: USEPA, A Review of the Reference Dose and Reference Concentration Processes, 630/P-02/002F at 4-12 (December 2002).] and to "use only data on humans for the exposure scenario of concern." [FN36: Supplementary Mixture Guidance at 85.] In addition, EPA has not finalized a human health toxicity assessment for either PFHxS or PFNA, and EPA's assessments for GenX and PFBS were not reviewed by the SAB or subject to appropriate peer-review, which has generally been required for all past MCLG and MCL proposals including those in this Proposal for PFOA and PFOS. High uncertainty factors can weight the HI to where knowledge is lacking most and evidence of additivity may be weakest, further demonstrating that this approach is not scientifically defensible. As these uncertainties are addressed, frequent revisions to the HI will be necessary, something not addressed in the Proposal.

Causing additional concern, the preamble to the Proposed Rule states that "additional PFAS can be added over time. . . . As such, this approach provides a framework for Federal and State public health agencies to consider using to address other PFAS in the future as needed." [FN37: 88 Fed. Reg. 18670.] EPA's guidance states that "as the number of compounds in the mixture increases, an assumption of additivity will become less reliable in estimating risk" [FN38: Mixture Guidelines at 26. This is particularly true where no common mode of action or target organ is required.] and "the uncertainty associated with the hazard index increases as the number of components increases, so that it is less appropriate for evaluating the toxicity of complex mixtures." [FN39: Mixture Guidelines at 27.] With estimates that there are thousands of PFAS substances, how and on what basis PFAS would be added to the HI calculation when the original four do not comply with EPA guidance demonstrates the arbitrary nature of this approach for these purposes. The HI approach results in an arbitrary and capricious "moving target" with an open-ended array of impossible compliance calculations and should be removed from the final rule.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Also, with respect to the use of animal studies, SDWA requires that to the degree that the EPA's action is based on science, the EPA must use "the best available, peer reviewed science" and "data collected by accepted methods or best available methods." The HBWCs/MCLGs are based on the best available science and data collected by accepted methods (see section III in the preamble and USEPA, 2024h). Specifically, peer-reviewed, publicly available toxicity assessments are available for HFPO-DA (USEPA, 2021e), PFBS (USEPA, 2021d), PFNA (ATSDR, 2021), and PFHxS (ATSDR, 2021) that provide the oral toxicity reference values (i.e., RfD or minimal risk level) used to calculate the HBWCs; the EPA selected the corresponding DWI-BW for the relevant sensitive population or life stage from the Exposure Factors Handbook (USEPA, 2019) based on the best available, peer-reviewed science from publicly available, peer-reviewed studies taking into account the relevant sensitive population(s) or life stage(s); and the RSCs are based on the best available, peer-reviewed science or best available methods taking into account the relevant sensitive population(s) or life stage(s)

(USEPA, 2000c). For example, the HFPO-DA and PFBS human health assessments underwent extensive peer-review, including internal EPA review, interagency review, independent external peer review, and public review and comment. As noted in the EPA's *Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a) and *A Review of the Reference Dose and Reference Concentration Process* (USEPA, 2002a), animal studies can provide the basis for toxicity reference values when adequate human studies are not available. Further, in the calculation of HBWCs, the DWI-BW values selected for each of the four PFAS takes into account the relevant sensitive population(s) or life stage(s); and RSCs are determined based on a literature review of potential exposure sources of the four PFAS (USEPA, 2000c). As it pertains to the portion of the comment regarding applicability of the Hazard Index to mixtures with increasing numbers of component chemicals, the text to which the commenter refers from the 1986 EPA Mixtures Guidelines is actually referring to similarity in 'toxic action' in support of an assumption of dose additivity. This is determined at the level of shared mode of action, whereas the Hazard Index is commonly applied under an assumption of dose additivity relaxed to the level of shared health effect/endpoint when MOA data are lacking, as in this case.

Regarding potential addition of PFAS, the EPA's final regulatory determination and final rule are limited to mixtures that include two or more of PFNA, PFHxS, PFBS, and HFPO-DA. If there is any potential future inclusion of additional PFAS under this approach, such inclusion would be the subject of a potential future regulatory process. For the EPA response to comments about the addition of PFAS to the HI calculation, please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-043433)

The Hazard Index approach is contrary to statutory requirements and EPA guidance.

The Proposed Rule would set an MCLG and MCL for PFNA, PFHxS, PFBS and GenX using an HI approach. Such an approach, however, is indefensible, being contrary to statutory requirements and EPA guidance. While HI's may be a routine component of contaminated site risk assessment, use of the HI to set a regulatory standard as set forth in the Proposal is novel and unsupportable, particularly given that it would have very broad applicability.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Superfund Settlements Project (SSP) and RCRA Corrective Action Project (RCAP) (Doc. #1631, SBC-043428)

Further, the novel HI approach proposed for these four PFAS is insupportable.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

National Association of Water Companies (NAWC) (Doc. #1670, SBC-044158)

Comments

1. The novel hazard index approach is not workable and should be withdrawn.

NAWC supports EPA's action to set MCL's for PFOA and PFOS at appropriate levels based on the available science while considering the costs to implement the MCL's because EPA's regulatory determination provides a basis for the proposed action. EPA's proposed preliminary determination to regulate four (4) additional PFAS chemicals, however, is based on a novel hazard index approach, lacks foundation, is inconsistent with the requirements of the Safe Drinking Water Act, sets a dangerous precedent, and should be withdrawn. EPA's preliminary regulatory determination to regulate: (1) PFHxS, (2) HFPO-DA and its ammonium salt (also known as a GenX chemicals), (3) PFNA, and (4) PFBS, and mixtures of these PFAS as contaminants under SDWA presents legal and technical questions about how it would be implemented.

Procedurally, EPA bypassed the important two-step process of the Safe Drinking Water Act by issuing the preliminary determination and the drinking water standard at the same time for these four contaminants. Moreover, the hazard index approach has never been used in settling an MCL and the proposed regulatory determination lacks factual support. The current health data do not support a proposed determination to regulate these four chemicals and their mixtures, either individually or as a mixture.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. For the EPA response to comments on the regulatory determination for the four PFAS, please see section 3 of the EPA response in this *Response to Comments* document.

New Hampshire Department of Environmental Services (NHDES) (Doc. #1690, SBC-044345)

Additionally, throughout EPA's proposed rule it emphasizes that the use of a Hazard Index is consistent with EPA regulatory activities despite not using this approach for regulation of drinking water contaminants as an MCL. EPA should, at a minimum, provide examples of where EPA has applied a Hazard Index as a regulatory action (not a screening level tool) for drinking water or other media that is regulated with similar authority. Furthermore, EPA should explain why the Hazard Index approach will be solely limited to a single class of chemicals (i.e., PFAS) instead of inclusion for other chemicals with similar effects on target organ systems. In several cases, Hazard Index approaches are applied to a variety of chemicals found at a site and not exclusively to a single "class" as applied in this proposed rule.

EPA Response: Although the EPA recognizes that the general Hazard Index has been used for several decades in at least one other regulatory context, the EPA is under no obligation to demonstrate that such an approach has previously been used in order to use such an approach in a SDWA rule. In fact, such an expectation would preclude the EPA from implementing the plain language of the SDWA, which requires the agency to use "best-available science." As

science is updated and develops, setting an artificial standard of "has the EPA done it exactly this way before?" would prevent the EPA's regulatory approaches from evolving with the science, thereby precluding the agency from using the best available science. As discussed elsewhere throughout the administrative record of this rulemaking action, the EPA maintains its statutory authority to regulate mixtures of PFHxS, PFNA, HFPO-DA, and/or PFBS, and if a mixture is considered a group, as some commenters suggest, Congress clearly contemplated that the EPA could regulated contaminants as groups. Please see section III of the preamble and section 3.2 of the EPA response in this *Response to Comments* document for further discussion. In this case, the agency has determined that use of a general Hazard Index for regulating mixtures of two or more of PFHxS, PFNA, HFPO-DA, and PFBS constitutes best available science as it considers the relative toxicity of the PFAS, and that the approach meets the agency's obligation to set an MCLG at a level where there are no known or anticipated adverse effects on the health of persons, allowing an adequate margin of safety. While it is recognized that any given site or exposure medium (e.g., water) may include a diverse landscape of environmental chemicals, in addition to PFAS, the expressed focus of the current NPDWR is on the PFAS indicated (i.e., HFPO-DA, PFBS, PFHxS, PFNA). And, although component-based mixtures methods such as the Hazard Index have previously been applied under site-specific assessment contexts (e.g., CERCLA), there is no indication in any existent EPA guidance that it cannot be used under other authorities (e.g., SDWA), and in fact, use of the approach generally has been supported by the SAB (please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document). The strength of the Hazard Index approach is flexibility in its application for chemicals for which exposure information (e.g., water concentration) and toxicity reference values (e.g., RfDs) are available. See also section 3 of the EPA response in this *Response to Comments* document about why the EPA selected these four PFAS for inclusion in the Hazard Index MCLG.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053345)

2. The Hazard Index does not meet SDWA's requirement to use best available science

a. The Hazard Index approach used is only appropriate for initial screening, not for regulation

The SAB was asked to review a mixtures framework, which contained multiple approaches for estimating the likelihood of noncancer risks associated with PFAS. EPA provided the SAB with descriptions of additivity-based approaches including the Hazard Index approach, a relative potency factor (RFP) approach, and a mixture-benchmark dose (M-BMD) approach. The framework document applied these approaches using a hypothetical mixture of five PFAS. EPA did not ask the SAB to review the framework as it is being applied in this proposed rule to PFNA, PFHxS, PFBS, and HFPO-DA as a mixture.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053350)

A Hazard Index approach that relies on different effects is not endorsed or supported by the SAB as being scientifically robust for a regulation. EPA has not explained why this screening level analysis is appropriate for an MCL, particularly since it is being used in a quantitative manner, to inform an economically significant regulation. Furthermore, EPA's own policy, as recently stated by the EPA Office of Chemical Safety and Pollution Prevention, is that the appropriate approach to addressing risks found in a screening level evaluation is to refine the evaluation [FN68: See EPA's Draft Proposed Principles of Cumulative Risk Assessment under the Toxic Substances Control Act, Feb. 2023, in which, when referring to assessing cumulative risk, EPA states, at page 14, that a "hierarchical approach" is used in which tiered exposure and hazard assessments are conducted and that "refinements are typically made when lower tier cumulative 483 assessments that rely on highly conservative assumptions do not demonstrate an adequate margin of 484 exposure (MOE)." When applying these same concepts to a HI approach, and a screening level approach shows concerns, additional refinements are appropriate. In this case, EPA has not provided any refinements. Available at: https://www.regulations.gov/document/EPA-HQ-OPPT-2022-0918-0008.]. It is not appropriate to use a screening level approach to inform regulation when additional information exists to inform the assessment.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053351)

EPA also notes that a Hazard Index approach is not novel because EPA uses it in the Superfund program [FN69: 88 Fed. Reg. at 18,669.]. But EPA's proposed use of a Hazard Index approach is inconsistent with Superfund program guidance. According to EPA's Risk Assessment Guidance for Superfund, the Hazard Index approach is most properly applied to compounds that produce the same effect by the same mode of action. If that condition is not met, the Superfund program guidance specifies that the Hazard Index should be used a screening tool only, just as the SAB had recommended [FN70: See Risk Assessment Guidance for Superfund Volume 1, Human Health Evaluation Manual (Part A), EPA/540/1-89/002, at 8-14, available at https://www.epa.gov/sites/default/files/2015-09/documents/rags_a.pdf.].

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053352)

b. The proposed Hazard Index approach is not appropriate because it blends different end points, is not best available science, and leads to illogical outcomes

The best available science with respect to setting a Hazard Index is to assess how the chemical affects a target organ, or an endpoint. Using this target organ-specific data within a Hazard Index framework is referred to as the TOSHI approach. In discussing this approach, the SAB stated: "The TOSHI approach presents additional robustness compared to the Screening Level HI given

the identification of human health/toxicity values that are effect/endpoint specific."[FN71: Id. at 92.] EPA nevertheless suggests that a TOSHI approach is less health protective [FN72: 88 Fed. Reg. at 18655.]. This is simply wrong. Target organ-specific reference values are derived to be protective against the adverse effect that occurs at the lowest level. If different contaminants have different target organ reference values, they can, and should, be evaluated separately. This is the scientifically robust approach to using the Hazard Index. The SAB recognized that target organ-specific information may be lacking for certain PFAS, which helped to inform why the approach EPA used was only recognized for initial screening. Even so, in the case of the four PFAS being proposed for regulation, EPA has target organ-specific data which the Agency could have used in a more refined manner. If the data are sufficient for setting HBWCs, then they should also be considered sufficient for a more refined Hazard Index approach [FN73: We note that a recent panel of independent experts deliberated on the most scientifically justified method of grouping PFAS for the purposes of human health risk assessment and regulatory actions and concluded that grouping PFAS together without data supporting common mode of action and potency is inappropriate. See Anderson, J.K. et.al., Grouping of PFAS for human health risk assessment: Findings from an independent panel of experts, Reg. Tox. Pharm, 2022, 134 (105226). Available at: https://www.sciencedirect.com/science/article/pii/S0273230022001131.].

Ignoring certain information available to it, EPA instead chose to use a screening level approach to derive an MCL and MCLG for mixtures of PFAS to inform this highly complex and economically significant proposed regulation. This, and the lack of presentation of this to the SAB, violates SDWA's mandate to use "the best available, peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices."[FN74: 42 U.S.C. [sec] 300g-1(b)(3)(A)(i).] EPA's explanation that the screening level approach, which is referred to as "general HI approach," is "a more health protective indicator of risk"[FN75: 88 Fed. Reg. at 18655.] does not eliminate its obligation to use best available science. SDWA mandates a rigorous science-driven approach to ensure the protection of health. It does not permit EPA to substitute a "reasonable policy choice"[FN76: Id. at 18655.] and forego a more rigorous analysis using data that is available.

EPA's screening level approach also leads to illogical outcomes. The Hazard Index may not be greater than 1.0. But if any of the individual PFAS occur at their HBWC, the ratio for that individual PFAS would be equal to 1. So, if two PFAS are at their HBWC (or even at half their HBWCs), the Hazard Index would be exceeded. In other words, the approach EPA has developed is so "health protective" that if even one PFAS is detected above its HBWC, the Hazard Index will be exceeded. This defeats the purpose of a mixtures approach because there are exceedances at detection levels before any additivity is considered. EPA's efforts to be "health protective" have led to an approach that is so restrictive that it makes any scientific evaluation irrelevant.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Regarding the comment that the "EPA has target organ-specific data which the Agency could have used in a more refined manner," this is incorrect. TTDs/target-organ

specific RfDs are not available for these four PFAS, and even if they were, the general Hazard Index is still the best approach to meet the statutory definition of MCLG.

American Water Works Association (AWWA) (Doc. #1759, SBC-045551)

3. The agency misuses the hazard index as a maximum contaminant level given it is not supported by federal guidance for assessing risk from mixtures and other issues.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

PFAS Regulatory Coalition (Doc. #1761, SBC-046071)

C. Use of the Hazard Index is inappropriate.

1. A Hazard Index does not meet the definition of an MCL.

The Safe Drinking Water Act defines MCL to mean: "the maximum permissible level of a contaminant in water which is delivered to any user of a public water system." SDWA Sec. 1401(3). Under the Hazard Index approach in the Proposal, EPA does not give a set "maximum permissible level." Instead, there is a range of levels for each of the four compounds, up to their respective "health-based water concentration" (HBWC), that could be either acceptable or unacceptable. The Proposal discusses how EPA has authority to regulate mixtures as "contaminants," but the examples that EPA provides are mixtures for which EPA has established fixed numbers. See 88 Fed. Reg. at 18644. EPA claims that it has authority to use a Hazard Index approach (see e.g., 88 Fed. Reg. at 18663), but EPA does not explain how a Hazard Index meets the SDWA definition of "maximum contaminant level."

2. A Hazard Index is not appropriate for compounds with different toxic modes of action.

A Hazard Index is not appropriate for compounds with different toxic modes of action. In this respect, the Hazard Index approach used in the Proposal is inconsistent with the approaches that are used in other EPA programs. EPA states that "the application of the HI approach under a regulatory purview is not novel," and the Agency cites CERCLA as an example of where the approach is used. 88 Fed. Reg. 18669. We agree that the HI approach is not novel, but what is novel is the very simplified approach EPA is using here. In EPA's 2000 "Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures," EPA lays out three approaches to conducting risk assessments for mixtures, recognizing how the state of the science influences which approach is appropriate. "Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures," EPA Risk Assessment Forum Technical Panel, August 2000, at p. xi (hereinafter "Supplementary Guidance").

In that Guidance, EPA further states that the "major concerns for the user are whether the available data are on components or whole mixtures, whether the data are composed of either similar components or similar mixtures that can be thought of as acting by similar toxicologic

processes, and whether the data may be grouped by emissions source, chemical structure, or biologic activity." Id. at xiv. Yet, in the EPA Proposal, the Agency provides no rationale as to why these four compounds can be grouped for a risk assessment that forms the basis of an HI. The EPA Proposal offers no support for a finding that these four additional PFAS compounds act by similar toxicologic processes or that they can be grouped by "emissions source, chemical structure, or biologic activity."

According to EPA's Risk Assessment Guidance for Superfund, the Hazard Index approach is most properly applied to compounds that produce the same effect by the same mode of action. If that condition is not met, the Hazard Index should be used as a screening tool only. See Risk Assessment Guidance for Superfund Volume 1, Human Health Evaluation Manual (Part A), EPA/540/1-89/002, at 8-14, available at https://www.epa.gov/sites/default/files/2015-09/documents/rags_a.pdf). If, absent data showing that the mode of action is the same, a Hazard Index should not be used to characterize risk at a Superfund site. Therefore, it certainly should not be used to establish a regulatory threshold.

The four PFAS species included in the proposed HI summation, PFNA, HFPO-DA, PFHxS, and PFBS, are dissimilar, and EPA presents no data confirming that the dose additivity model applies to these compounds. In the Supplementary Guidance referenced above, EPA explains that the "term additivity is used when the effect of the combination of chemicals can be estimated directly from the sum of the scaled exposure levels (dose addition) or of the responses (response addition) of the individual components." Supplementary Guidance, at 10. EPA's Proposal merely assumes additivity without adhering to either of the scientifically supported analytical approaches set forth in the Supplementary Guidance.

Further, EPA's additivity approach in the Proposal appears to prejudge issues that EPA is still considering as to PFAS compounds in other programs. In the CERCLA ANPRM issued in April 2023, EPA is specifically soliciting feedback on whether future CERCLA action could group PFAS compounds, including on the basis of modes of toxicological action:

EPA is considering whether to initiate a future action that would potentially designate groups or categories of PFAS as hazardous substances. A group or category refers to a set of PFAS that share one or more similar characteristics. Characteristics of interest could include, but are not limited to, chemical structure (e.g., carbon chain length, functional group), physical and chemical properties, mode of toxicological action, precursors or degradants, or co-occurrence.

88 Fed. Reg. 22402-403 (emphasis added). EPA then gives an example of a Significant New Use Rule (SNUR) issued under the Toxic Substances Control Act (TSCA), in which grouping was based on chemical structure. 88 Fed. Reg. 22403.

In the TSCA program, EPA has developed Draft Principles for Cumulative Risk Assessment (CRA; Link: https://www.epa.gov/assessing-and-managing-chemicals-under-tsca/cumulative-risk-assessment-under-toxic-substances). In that draft document, EPA bases additivity on toxicological similarity: "Deciding, based on their toxicological similarity, which chemical substances to include in a cumulative chemical group that subsequently would be evaluated

using dose additive models is an important element of a CRA." Draft Principles for Cumulative Risk Assessment, EPA Document # EPA-740-P-23-001, Feb. 2023, United States Office of Chemical Safety and Environmental Protection Agency, Pollution Prevention, lines 458460, available at https://www.epa.gov/assessing-and-managing-chemicals-undertsca/cumulative-risk-assessment-under-toxic-substances. The four additional PFAS addressed in the EPA Proposal are not toxicologically similar, so EPA grouping them here is inconsistent with how EPA would group these chemicals under TSCA.

In sum, the Proposal provides no basis for grouping these four compounds through use of a Hazard Index. EPA tries to justify the grouping by co-occurrence, but that justification is not scientifically supported. As discussed in Section A.2 above, we do not believe that co-occurrence is supported by the data. Simply put, a Hazard Index of compounds that share nothing other than being part of a larger class is meaningless. Moreover, the inconsistency between EPA's Proposal and the rationale for the use of dose additivity in other programs, such as CERCLA and TSCA, supports that conclusion that use of an HI as a surrogate for an MCL for these four compounds is arbitrary and capricious.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. Additionally, commenter is incorrect that the EPA does not provide a specific permissible maximum contaminant "level" with the Hazard Index MCL. The Hazard Index is set at a unitless value or level of 1. The EPA provides clear regulatory instructions for how to calculate whether the mixture is in compliance with that level. Regarding the EPA's rationale for considering these four contaminants as a mixture and the statutory authority for regulation of mixtures, please see section III.A.2 of the final rule preamble and section 3.2 of the EPA response in this *Response to Comments* document. Furthermore, as discussed in section 3 of this *Response to Comments* document, the EPA disagrees that it has not provided the statutory basis for regulation of mixture combinations of these four PFAS and that this justification is not scientifically supported through the best available information informing the EPA's regulatory determination. Specifically pertaining to co-occurrence information, please see sections 3.2.2 and 6.3 of the EPA response in this *Response to Comments* document.

U.S. Poultry & Egg Association et al. (Doc. #1765, SBC-044548)

4. The use of a Hazzard Index to regulate "levels" of PFAS Mixtures

In the proposed regulation, EPA is requesting comment on a preliminary determination to regulate additional PFAS referred to as ''GenX Chemicals," PFNA, and PFBS. EPA proposes to use a "Hazard Index" (HI) approach to protecting public health from these mixtures because of their known and additive toxic effects and occurrence and likely co-occurrence in drinking water.

The Agency has indicated the HI will be established as the total of component PFAS HQs, calculated by dividing the measured component PFAS concentration in water by the relevant Health Based Water Concentration (HBWC.) In this proposal, EPA is using HBWCs of 9.0 ppt for PFHxS, 10.0 ppt. The proposed regulations states "EPA is proposing an HI of 1.0 as the

MCLGs for these four PFAS and any mixture containing one or more of them because it represents a level at which no known or anticipated adverse effects on the health of persons is expected to occur and which allows for an adequate margin of safety."

According to the National Drinking Water Regulations, contaminants that EPA regulates through the issuance of a final regulatory determination, the contaminant identified must be regulated by issuing a MCL or, "if it is not economically or technically feasible to so ascertain the level of such contaminate," to employ a treatment technique.

The Safe Drinking Water Act (SDWA) requires the use of MCLs and MCLGs with specified levels to provide regulated entities with the information it needs to comply with the regulation. The HI scheme EPA proposes provides no level to guide the adoption of a treatment technique. Rather the HI is a sum of component hazard quotients, calculated by dividing the measured regulated PFAS component contaminant concentration in water by the associated health-based water concentration. This approach would bring a high level of uncertainty to the regulated community because of the variability that will occur from revising the health-based water concentrations.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

American Water Works Company Inc. (Doc. #1608, SBC-043990)

Use of the Hazard Index Approach to Regulate PFHxS, HFPO-DA, PFNA, and PFBS

American Water does not support the use of the Hazard Index as proposed for regulating PFAS in drinking water and recommends the development of drinking water regulations that follow the MCL approach. We understand the U.S. EPA's effort to manage multiple PFAS analytes through a single approach, and the fact that this approach is used in other environmental programs, but American Water has concerns about the application within drinking water.

The U.S. EPA is proposing to use the general Hazard Index approach that essentially adds together all PFAS regardless of the method of impact or health endpoint. As the U.S. EPA indicates, this approach is more conservative but lends itself to potentially inappropriate addition of health effects that should not be combined.

The use of the target-organ specific Hazard Index is anticipated to be less conservative but would be more consistent with an actual dose additive approach since the approach "…relies on toxicity value aggregated by the "same target organ endpoint/effect…" (Page 18655). American Water also notes that the preamble indicates that the target-organ specific Hazard Index requires a health-specific reference dose (RfD) in order to be used, which is consistent with our earlier comments regarding the need for consistent health effects information.

The examples below illustrate how the preamble is unclear on whether the Science Advisory Board explicitly reviewed and opined on the general Hazard Index Approach as proposed or the concept in general. The U.S. EPA should be transparent on this matter in the final rule.

"EPA's Science Advisory Board (SAB) opined that where the health endpoints of the chosen compounds are similar, it is reasonable to use an HI as ''a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media.'' (USEPA, 2022a). (Page 18639)

"EPA's SAB opined that where the health endpoints of the chosen compounds are similar, ''the HI methodology is a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media. The HI is an approach based on dose additivity (DA) that has been validated and used by EPA'' (USEPA, 2022a)." (Page 18654)

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

American Water Works Company Inc. (Doc. #1608, SBC-043983)

Use of the Hazard Index Approach to Regulate PFHxS, HFPO-DA, PFNA, and PFBS – American Water does not support the use of the Hazard Index as proposed for regulating PFAS in drinking water and recommends the development of drinking water regulations that follow the MCL approach once data to support such action is available.

EPA Response: Please see sections 4.3.2 and 3 of the EPA response in this *Response to Comments* document.

Raptor Pharm & Tox, Ltd (Doc. #1644, SBC-043419)

Hazard Index Approach Is Not Yet Justified

Raptor believes US EPA's hazard index approach to dose additivity is highly inappropriate given the current state of the science. In order for a hazard index approach to be appropriate, the chemicals must have dose-response curves that demonstrate the same efficacy, and the same overall shape of the curve, with only the potency being different. In other words, the curves need to have a correlation coefficient very close to 1, with the same efficacy. Violations of these assumptions makes the hazard index overly-conservative or not conservative enough. In other words, violations of the assumptions make the hazard index not scientifically justifiable.

Rather, the US EPA must avoid the use of the hazard index approach, as the US EPA has not given sufficient evidence to justify the approach. Using the hazard index without scientific justification will be a violation of the Safe Drinking Water Act.

Instead, Raptor recommends that US EPA and its partners at the US National Toxicology Program put together a mixtures study at human relevant concentrations, and at concentrations

near the final drinking water standard (which Raptor will note should not be the ones being proposed by the US EPA in this draft; rather, the final ones should be much higher, more in line with the value calculated by an international collaboration of risk assessors that recently proposed a more appropriate value).

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Regarding the suggestion that "US EPA and its partners at the US National Toxicology Program put together a mixtures study at human relevant concentrations," the EPA's final rule represents data-driven drinking water standards that are based on the best available science and meet the requirements of SDWA. For the six PFAS, the EPA considered PFAS health effects information, evidence supporting dose-additive health concerns from co-occurring PFAS, as well as national and state data for the levels of multiple PFAS in finished drinking water. SDWA provides a framework for the EPA to regulate emerging contaminants of concern in drinking water. Under the statute, the EPA must act based on the "best available" science and information. Thus, the statute recognizes that the EPA may act in the face of imperfect information. It also provides a mechanism for the EPA to update standards as more science becomes available. For the PFAS covered by this rule, the EPA concluded that the state of the science and information has sufficiently advanced to the point to satisfy the statutory requirements and fulfill SDWA's purpose to protect public health by addressing contaminants in the nation's PWSs.

The commenter's supposition about "chemicals must have dose-response curves that demonstrate the same efficacy, and the same overall shape of the curve, with only the potency being different" is true for application of the general Hazard Index specifically when all components have MOA data for the same effect/endpoint; the general Hazard Index does not require this to be met for application of dose additivity to a mixture of chemicals. This clarification is captured in text box 2.6.1.1 in the EPA's 2000 Supplemental Mixtures Guidance (USEPA, 2000b) where "The 'common mode-of-action' assumption can be met by using a surrogate of same target organ."

3M Company (Doc. #1774, SBC-045674)

e. EPA's Unprecedented Hazard Index Approach Violates the SDWA and is Arbitrary

EPA's proposal to regulate drinking water concentrations for the HI PFAS using the so-called "general HI approach" is arbitrary, not based on sound scientific principles, and does not conform with long-standing risk assessment practices and toxicological principles detailed in EPA's human health risk assessment guidance (USEPA 1986, 1989, 2000b). Further, the use of the general HI approach is at odds with methods currently employed in some EPA regulatory programs, and the adoption of this approach for use in National Primary Drinking Water Regulations (NPDWR) would introduce conflicting outcomes depending on PFAS present and their relative concentrations.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Given the temporal and spatial variability of PFAS occurrence in drinking water across the nation (USEPA, 2024j), it is appropriate to regulate these chemicals in drinking water by taking a flexible approach such as the general Hazard Index that considers site-specific occurrence data at each PWS. Component PFAS HQs are expected to differ across time and space depending on the actual measured concentrations of each of the four PFAS. This approach allows for flexibility beyond a one-size-fits-all approach and is tailored to address risk at each PWS.

American Chemistry Council (ACC) (Doc. #1841, SBC-052932)

A recent panel of independent experts deliberated on the most scientifically justified method of grouping PFAS for the purposes of human health risk assessment and regulatory actions and concluded that grouping PFAS together without data supporting common MOA and potency is inappropriate (Anderson et al., 2022). This panel of experts agreed that the HI dose additivity assumption for PFAS may be appropriate for screening (i.e., to determine if no risk or if further analysis is needed), but the data gaps currently present result in a high degree of uncertainty.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-052934)

EPA Mischaracterizes the Recommendations of its Science Advisory Board on the Application of a Hazard Index

In its review of EPA's proposed approach to PFAS mixtures, the SAB identified several cautions that are not reflected in the Agency's current proposal for a HI approach for the four PFAS. Of primary importance is the Board's answer to the charge question regarding the approach to which it responded that it "agrees with the use of Hazard Index (HI) as a screening method and decision-making tool." The Panel further explains –

In general, the screening level HI approach, in which Reference Values (RfVs) for the mixture components are used regardless of the effect on which the RfVs are based, is appropriate for initial screening of whether exposure to a mixture of PFAS poses a potential risk that should be further evaluated. [FN150: USEPA SAB Review, at 91.]

In fact, the most recent HI approach guidance from the EPA, as well as other U.S. agencies and international authorities, is to utilize the default HI approach as a preliminary screening step of a more comprehensive tiered methodology. [FN151: USEPA. Concepts, Methods, and Data Sources for Cumulative Health Risk Assessment of 584 Multiple Chemicals, Exposures, and Effects: A Resource Document. EPA/600/R-585 06/013F. Office of Research and Development (2007).] If the preliminary screening indicates there is a potential for risk (i.e., if HI>1), further

evaluation is recommended using "Tier 1 or 2" approaches, which include using target organ-specific HIs or the Target Organ Toxicity Dose (TTD) HI approach.

Yet, the Agency is proposing to abandon the need for further evaluation and to use the HI based on different health endpoints as the basis for regulation. This approach is counter, not only to the Board's advice, but also to the Agency's 2000 Supplementary Mixtures Guidance, 2007 guidance of cumulative risk, and to the recently proposed principles for cumulative risk assessment under the Toxic Substances Control Act (TSCA). [FN152: USEPA. Draft Proposed Principles of Cumulative Risk Assessment under the Toxic Substances Control Act. Public Comment Draft. EPA-740-P-23-001. Office of Chemical Safety and Pollution Prevention (2023). (USEPA Draft TSCA Cumulative Risk Principles)] Meek et al. have outlined an appropriate framework for evaluating combined exposure to multiple chemicals, using a tiered approach that incorporates additional information with each tier. [FN153: Meek ME et al. Risk assessment of combined exposure to multiple chemicals: A WHO/IPCS framework. Reg Toxicol Pharma 60:S1-S14 (2011).]

Rather than focus on the Board's recommendation to use the proposed HI for the four PFAS as a screening tool, the Agency characterization of the "generally favorable review" from the Board is based on the following language -

The SAB PFAS Review Panel supports dose additivity based on a common outcome, instead of a common mode of action as a health protective default assumption and does not propose another default approach. [FN154: USEPA SAB Review, at 90.]

Other than offer generalized statements, EPA has provided no evidence to support a "common outcome" among the endpoints selected for the four PFAS. [FN155: Interestingly, EPA's draft TSCA Cumulative Risk Principles suggest that assessing mixtures based on an effect on the same target organ may introduce too much uncertainty to risk estimates. USEPA TSCA Draft Cumulative Risk Principles, at 10.] The Agency's statement that its proposed HI is "a more protective indicator of risk," is neither scientifically supportable nor consistent with long-standing EPA policy on mixtures.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document.

Missouri Department of Natural Resources (Doc. #1563, SBC-042517)

Section V—Maximum Contaminant Level Goal

EPA requests comment on the general HI approach for the mixture of four PFAS. The Department has concerns with the general HI approach identified by EPA in the rule. The HI is a new concept for drinking water regulation and would add complexity to rules that are already significantly more difficult for small systems with limited resources to comply with. While the Department agrees that different PFAS could have a cumulative impact, EPA needs to ensure that the health effect endpoints for any PFAS included in the index are in the same order of

magnitude to have meaningful additive health effects. If EPA proceeds with the HI approach, the Department agrees with EPA's Science Advisory Board (SAB) where they opined, "where the health endpoints of the chosen compounds are similar, it is reasonable to use an HI as a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media." However, the proposed HI does not include similar health endpoints as three analytes have a health based water concentration (HBWC) near 10 ppt and one has a HBWC at 2000 ppt. Further, EPA has not shown the aggregate health hazards are at similar concentrations. It matters if the aggregate health hazards are at 50%, 10% or only 1% of the set HBWC which is calculated the same as a lifetime health advisory level.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. The EPA disagrees with the assertion that in order to establish a Hazard Index MCLG for the PFAS mixture, the HBWCs of the individual mixture components must have similar orders of magnitude. There is no scientific or mathematical basis to suggest that HBWCs must be similar in magnitude. The use of the most scientifically sound, health-protective HBWCs in the development of a Hazard Index, regardless of whether they differ in magnitude, is consistent with EPA chemical mixtures guidance (USEPA, 2000b) as well as the EPA's obligation under SDWA (Section 1412(b)(4)(A)) to set MCLGs at "the level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety." The commenter appears to misunderstand the definition of HBWC and the practical application of the general Hazard Index approach in the context of the NPDWR. The general Hazard Index accounts for the combined effects of the different mixture components and compares the exposure level of each component to that component's corresponding HBWC, which is based on the most sensitive known adverse health outcome (as supported by the weight of evidence) for that component. In this context, the HBWC is the level below which adverse health effects over a lifetime of exposure are not expected to occur, including for sensitive populations and life stages. This level also meets the statutory definition of an MCLG, which is the level of a contaminant below which there are no known or adverse effects with an adequate margin of safety.

The proposal defined a mixture as containing one or more of the four PFAS and therefore covered each contaminant individually if only one of the four PFAS occurred. Thus, the general Hazard Index as proposed ensures that the level of exposure to an individual PFAS remains below that which could impact human health because the exposure for that measured PFAS is divided by its corresponding HBWC. In the general Hazard Index approach, individual PFAS HQs are calculated by dividing the measured concentration of each mixture component PFAS in water (e.g., expressed as ng/L) by the corresponding HBWC for each component PFAS (e.g., expressed as ng/L), and the results are summed to derive a Hazard Index. The HBWC is akin to an MCLG in that it reflects a level below which there are no known or anticipated adverse effects over a lifetime of exposure, including for sensitive populations and life stages, and allows for an adequate margin of safety. The general Hazard Index approach ensures that the level of exposure to a PFAS mixture remains below that which could adversely impact human health. It

incorporates health protection afforded by the HBWCs for the individual PFAS mixture components as well as the resulting Hazard Index itself, which provides an adequate margin of safety with respect to potential health hazards of mixtures of these PFAS.

With respect to the comment about HAs as a basis for HBWCs: HA are not a pre-requisite for an NPDWR under SDWA and there is nothing in the statute or the EPA's historical regulatory practice that suggests that the agency must or should delay regulation of a contaminant in order to develop a HA first. Further, the HAs for HFPO-DA and PFBS are not a basis or the starting point for their respective HBWCs. The EPA acknowledges that the HAs and HBWCs have been set at the same level, but the EPA's HBWCs for HFPO-DA and PFBS represent its conclusions at the time of the rulemaking to calculate the HBWC using identified RfDs, to select the identified DWI-BWs, and apply the RSCs of 0.20.

Missouri Department of Natural Resources (Doc. #1563, SBC-042520)

EPA requests comment on whether the HBWCs should instead be proposed as stand-alone MCLGs in addition to or in lieu of the mixture MCLGs.

The Department views HBWCs as just a renaming of lifetime health advisory levels (HAL). As can be seen in the most recent 2018 health advisory tables (2018 Edition of the Drinking Water Standards and Health Advisories Tables (EPA 822-F-18-001) [Link-https://www.epa.gov/system/files/documents/2022-01/dwtable2018.pdf]), most analytes have a lifetime health advisory level equal to the MCLG. If EPA proceeds with a PFAS mixture MCLG, the individual PFAS analytes compared in the mixture must have similar orders of magnitude (e.g., not 10 ppt vs 2000 ppt) as part of the mixture.

EPA Response: Please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. The HAs for HFPO-DA and PFBS are not a basis or the starting point for their respective HBWCs. The EPA acknowledges that the HAs and HBWCs have been set at the same level, but the EPA's HBWCs for HFPO-DA and PFBS represent its conclusions at the time of the rulemaking to calculate the HBWC using identified RfDs, to select the identified DWI-BWs, and apply the RSCs of 0.20.

The EPA disagrees with the assertion that in order to establish a Hazard Index MCLG for the PFAS mixture, the HBWCs of the individual mixture components must have similar orders of magnitude. There is no scientific or mathematical basis to suggest that HBWCs must be similar in magnitude. The use of the most scientifically sound, health-protective HBWCs in the development of a Hazard Index, regardless of whether they differ in magnitude, is consistent with the EPA's chemical mixtures guidance (USEPA, 2000b) as well as the EPA's obligation under SDWA (Section 1412(b)(4)(A)) to set MCLGs at "the level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety." The commenter appears to misunderstand the definition of HBWC and the practical application of the Hazard Index in the context of the NPDWR. The Hazard Index accounts for the combined effects of the different mixture components and compares the exposure level of

each component to that component's corresponding HBWC, which is based on the most sensitive known adverse health outcome for that component. In this context, the HBWC is the level below which adverse health effects over a lifetime of exposure are not expected to occur, including for sensitive populations and life stages. This level also meets the statutory definition of an MCLG, which is the level of a contaminant below which there are no known or anticipated adverse effects with an adequate margin of safety.

The proposal defined a mixture as containing one or more of the four PFAS and therefore covered each contaminant individually if only one of the four PFAS occurred. Thus, the general Hazard Index as proposed ensures that the level of exposure to an individual PFAS remains below that which could impact human health because the exposure for that measured PFAS is divided by its corresponding HBWC. In the general Hazard Index approach, individual PFAS HQs are calculated by dividing the measured concentration of each mixture component PFAS in water (e.g., expressed as ng/L) by the corresponding HBWC for each component PFAS (e.g., expressed as ng/L), and the results are summed to derive a Hazard Index. The HBWC is akin to an MCLG in that it reflects a level below which there are no known or anticipated adverse effects over a lifetime of exposure, including for sensitive populations and life stages, and allows for an adequate margin of safety. The general Hazard Index approach ensures that the level of exposure to a PFAS mixture remains below that which could adversely impact human health. It incorporates health protection afforded by the HBWCs for the individual PFAS mixture components as well as the resulting Hazard Index itself, which provides an adequate margin of safety with respect to potential health hazards of mixtures of these PFAS.

Water Works Board of the City of Birmingham (BWWB) (Doc. #1602, SBC-052866)

2. Inconsistency of the health advisories (HA) for the regulated compounds: PFBS and GenX have HAs; PFOA and PFOS have "interim" HAs; and PFNA and PFHxS do not have HAs. However, MCLs based on health effects are proposed for all six PFAS compounds.

Although it is understandable that the development of HAs is an ongoing process, the inconsistency of HA status (i.e., HA, "interim" HA, no HA) amongst PFAS species may cause confusion amongst the public. Moreover, the public may need additional clarity on how the EPA has proposed MCLs based on health effects for the six (6) compounds in the proposed PFAS Rule, in spite of not having established HA's for each. It is recommended that the USEPA provide additional insight on how the MCL was determined per PFAS species.

EPA Response: The EPA disagrees with this comment. HAs are issued under a separate statutory authority and are not a pre-requisite for an NPDWR under the SDWA.

Horsham Water & Sewer Authority (HWSA) (Doc. #1686, SBC-043807)

We also have concerns to the appropriateness of the proposed Hazard Index MCL for the combination of perfluorohexanesulfonic (PFHxS), perfuorononanoic acid (PFNA),

perfluorobutanesulfonic acid (PFBS) and hexafluoropropylene oxide dimer acid (HFPO-DA or GenX).

EPA Response: Please see sections 4.3.2 and 5 of the EPA response in this *Response to Comments* document.

Protecting Our Water, Environment, and Ratepayers (POWER) (Doc. #1714, SBC-045941)

Even if the grouping were permitted, there is no authority for using a Hazard Index in this context.

The Hazard Index is traditionally used in the context of CERCLA to inform the target risk levels. Here, EPA is proposing to use a Hazard Index in the context of the SDWA, which has not been done before. In its proposed rule, EPA does not explain the authority for using the Hazard Index in the context of the SDWA and simply asserts that it should be allowed because this is not a new regulatory preview. Simply asserting that the Hazard Index is not new does not sufficiently explain the authority for the EPA to use the Hazard Index in setting an MCL and MCLG under a different statutory scheme.

The data needed to support the Hazard Index formation are not yet finalized.

The Hazard Index typically refers to the risk level as a sum of the Hazard Quotient ("HQ"). The HQ is the ratio of the exposure level of a simple substance to the Reference Dose ("RfD"). The RfD comes from the human health toxicity assessment."[FN24: EPA, Human Health Toxicity Assessments for GenX Chemicals (last updated Dec. 27.2022) (https://www.epa.gov/chemical-research/human-health-toxicity-assessments-genx-chemicals)]

In the proposed NPDWR, EPA acknowledges that the human health toxicity assessments for PFHxS and PFNA are currently ongoing and are supposed to undergo public comment this year. Because the human health toxicity assessment has yet to be released, neither PFHxS nor PFNA have a finalized RfD that can be used to calculate the HQ or the Hazard Index. Setting the Hazard Index with RfD information that is not finalized and is subject to public comment in the following months would be arbitrary.

The proposed Hazard Index is not supported by SDWA precedent or science. EPA should propose MCLs for PFHxS, HFPO-DA, PFNA, and PFBS only after it has taken and finalized the steps available under the SDWA to ensure the proposals are grounded in sound science.

EPA Response: Please see sections 4.3.2 and 4.3.3 of the EPA response in this *Response to Comments* document. Additionally, the EPA's final rule represents data-driven drinking water standards that are based on the best available science and meet the requirements of SDWA. For the six PFAS, the EPA considered PFAS health effects information, evidence supporting dose-additive health effects from co-occurring PFAS, as well as national and state data for the levels of multiple PFAS in finished drinking water. SDWA provides a framework for the EPA to regulate emerging contaminants of concern in drinking water. Under the statute, the EPA must

act based on the "best available" science and information. Thus, the statute recognizes that the EPA may act in the face of imperfect information. It provides a mechanism for the EPA to update standards as more science becomes available. For the PFAS covered by this rule, the EPA concluded that the state of the science and information has sufficiently advanced to the point to satisfy the statutory requirements and fulfill SDWA's purpose to protect public health by addressing contaminants in the nation's PWSs.

Louisville Water Company (Doc. #1720, SBC-043556)

[In that regard, we are providing the following comments on key issues that we think require consideration.]

6. Louisville Water is committed to providing its customers with the best water quality as is reasonably possible. We establish internal treatment goals well below regulatory thresholds and expectations. However, we strongly oppose the proposed approach of using the Hazard Index (HI) as a compliance standard because this approach is, in effect, more stringent than the Maximum Contaminant Level Goal (MCLG). We are concerned with the precedent being set regarding the agency using the HI to calculate the MCL for PFNA, PFBS, PFHxS, and GenX. It is questionable, if not fundamentally flawed, to use the HI as an MCL. HI is a risk-screening tool used to estimate the total health risk for a mixture of contaminants. The HI is the calculated sum of component hazard quotients (HQs). HQ is the component contaminant concentration divided by the associated HBWC. (The calculated HBWC is essentially the same as the MCLG.) Therefore, the HI is a MCLG-based matrix and is more stringent than individual MCLG. According to EPA's definition, the MCL is "the highest level of a contaminant that is allowed in drinking water and is established as close to MCLGs as feasible using the best available treatment technology and taking cost into consideration" (see below). In this case, using an HI as an MCL results in an MCL that is more stringent than individual MCLGs, which is not consistent with the definition and intention of the MCL. In addition, EPA chose a general HI which allows for component chemicals in the mixture to have different health effects or endpoints as the basis for the component chemical reference values (e.g., RfDs). This general HI approach is best used as a risk screening level and not as an enforceable standard. If the agency continues to use the HI approach, which we believe is fundamentally flawed and which we strongly oppose, EPA may consider the target- organ specific HI which relies on reference values based on the same organ or organ system (e.g., liver-, thyroid-, or developmental-specific). Finally, the four additional PFAS may require very different treatment approaches. The proposed HI/MCL for the four PFAS includes two long-chain PFAS (PFNA and PFHxS) and two short-chain PFAS (PFBS and HFPO-DA). We know that granular activated carbon and Ion Exchange (IX) are generally not cost-effective for removing short-chain PFAS due to the short bed life. Reverse Osmosis (RO) is effective for all PFAS treatment but is cost-prohibitive for use by many utilities. Louisville Water is concerned that using the proposed HI as an MCL sets an inappropriate precedent that contradicts the SDWA's intention with regarding the MCLs and the use of MCLGs. EPA's use of the HI as an MCL also fails to provide for consideration of feasibility/cost in rulemaking which is considered using a traditional MCLG/MCL approach.

EPA Response: Please see sections 4.3.1, 4.3.2, and 10 of the EPA response in this *Response to Comments* document. Regarding the commenter's statement that the Hazard Index MCL is more stringent than the Hazard Index MCLG, the agency disagrees because as discussed in section V of the final rule preamble, the Hazard Index MCLG is 1 and the Hazard Index MCL is being set as close a feasible to that level. In this case, based on the EPA's determination of feasibility, the Hazard Index MCL is set to the same level as the MCLG (Hazard Index value of 1), but it is not more stringent. The EPA also clarifies that within the Hazard Index the individual HBWCs and respective concentrations of each of the four PFAS are considered collectively to evaluate mixtures containing two or more of the Hazard Index PFAS; thus, they are not treated as individual MCLGs. For additional discussion on feasibility of the final MCLs promulgated in this NPDWR, please see sections 5.1, 5.2, and 5.3 of the EPA response in this *Response to Comments* document.

Massachusetts Department of Environmental Protection (MassDEP) (Doc. #1726, SBC-045175)

7. Evaluation of Toxicology and Scientific Basis for Standard Setting

MassDEP has several comments on EPA's proposed HI approach and the derivation of the MCLG, including comments on the draft document entitled "Maximum Contaminant Level Goal (MCLG) Summary Document for a Mixture of Four Per- and Polyfluoroalkyl Substances (PFAS): HFPO-DA and its Ammonium Salt (also known as GenX Chemicals), PFBS, PFNA, and PFHxS [FN1: EPA 2023a. Maximum Contaminant Level Goal (MCLG) Summary Document for a Mixture of Four Per- and Polyfluoroalkyl Substances (PFAS): HFPO-DA and its Ammonium Salt (also known as GenX Chemicals), PFBS, PFNA, and PFHxS, Public Review Draft. U.S. Environmental Protection Agency, Office of Water (4304T), Office of Science and Technology, Health and Ecological Criteria Division, Washington, DC 20460. EPA-822-P-23-004.]," (hereinafter referred to as the "Mixture document") which serves as a basis of EPA's proposed HI approach. Specifically, our comments address the following: (1) inclusion of additional PFAS in the HI; (2) use of body weight- adjusted drinking water intakes (DWI-BWs) in establishing the MCLG; (3) the calculation of the PFHxS health-based water concentration (HBWC); (4) the application of potency subgroups to the HI; (5) identification and use of the PQL in establishing the PFOS and PFOA proposed MCLs; and (6) the compliance averaging period.

EPA Response: Please see sections 4.3.2, 4.3.3, and 7, and 8 of the EPA response in this *Response to Comments* document.

LSP Association (LSPA) (Doc. #1742, SBC-043598)

The Hazard Index Approach is confusing to the lay person without risk assessment experience. The LSPA urges USEPA to consider using a summed concentration approach for PFNA, GenX, and PFHxS similar to that which MassDEP has employed for six PFAS compounds of similar toxicity (i.e., in Massachusetts, the MCL for the sum of the concentrations for these six PFAS

compounds is 20 ppt). For PFNA, GenX, and PFHxS, using the current EPA toxicity values, a summed concentration of 10 ppt would be roughly equivalent to a Hazard Index of 1.

EPA Response: Please see sections 4.3.2 and 5 of the EPA response in this *Response to Comments* document.

Connecticut Department of Public Health (CT DPH) (Doc. #1745, SBC-045211)

3. EPA requests comment on the general HI approach for the mixture of four PFAS.

CT DPH agrees that regulating co-occurring PFAS using the HI approach is more protective than regulating the individual PFAS. However, EPA should address the three points below, before using the HI approach in its final regulatory decision:

EPA Response: The EPA agrees that using the Hazard Index approach is more protective than regulating the individual PFAS alone. Please see section 4.3.2 of the EPA response in this *Response to Comments* document. (The EPA responses to the commenter's three points referenced above are included with other comments from this commenter).

Connecticut Department of Public Health (CT DPH) (Doc. #1745, SBC-045213)

b) CT DPH is aware of the data gap to develop target-organ specific HIs and EPA's statement "a target-organ specific HI approach relies on toxicity values aggregated by the 'same' target organ endpoint/effect, and the absence of information about a specific endpoint may result in the contaminant not being adequately considered in a target-organ specific approach, and thus, underestimating potential health risk". However, this underestimation of risk is due to the data gap itself rather than the use of the target-organ specific HI approach. EPA excluded using a single target-organ specific HI for the regulation but did not discuss whether it is possible to evaluate multiple target-organ specific HIs collectively (i.e. making the MCL determination based on exceeding ANY of several target-organ specific HIs). For example, a HI based on thyroid effect can be calculated using the formula HIthyroid=HQthyroid[PFHxS]+HQthyroid[PFBS], PFNA and GenX do not need to be included in this calculation because there is less adequate data to indicate they have thyroid effect. The HIs based on developmental and liver effects (and other effects, if data availability allow), can be calculated in a similar manner. Any of the HIs larger than 1 would indicate a potential health risk.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. The TOSHI produces a less health-protective indicator of risk than the general Hazard Index because the basis for the mixture component toxicity reference values in a TOSHI has been limited to a specific target organ or system effect, which may occur at higher exposure levels than other effects (i.e., be a less sensitive endpoint). Additionally, since a TOSHI relies on toxicity reference values aggregated for the same specific target organ or system endpoint/effect, an absence or lack of data on the specific target organ or system endpoint/effect for a mixture component may result in that component not being adequately accounted for in this approach

(thus, underestimating health risk of the mixture). A TOSHI can only be derived for those PFAS for which the same target organ or system endpoint/effect-specific RfDs have been calculated. Many PFAS have data gaps in epidemiological or animal toxicological dose-response information for multiple types of health effects, thus limiting derivation of target organ-specific toxicity reference values; target organ-specific toxicity reference values are not currently available for PFHxS, PFNA, HFPO-DA, and PFBS. The EPA's *Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures* recognizes the potential for organ- or system-specific data gaps and supports use of overall RfDs in a general Hazard Index approach, stating, "The target organ toxicity dose (TTD) is not a commonly evaluated measure and currently there is no official EPA activity deriving these values, as there is for the RfD and RfC" … "Because of their much wider availability than TTDs, standardized development process including peer review, and official stature, the RfD and RfC are recommended for use in the default procedure for the HI" (USEPA, 2000b).

The commenter's example of a TOSHI based on thyroid effects which only includes PFHxS and PFBS (and excludes HFPO-DA and PFNA) perfectly illustrates why the target organ-specific approach (TOSHI) underestimates risk. Studies show that HFPO-DA and PFNA significantly affect the thyroid (please see section 4.3.1 of this *Response to Comments* document). According to the Interagency Report to Congress on PFAS, "Multiple studies on diverse species (developing rodents and fish) suggest that some PFAS (e.g., PFOS, PFOA, *PFNA, GenX chemicals*, PFHxS, PFDA, PFBA, PFBS, PFHxA) interfere with thyroid hormone signaling pathways and thyroid homeostasis through various mechanisms, including regulation of hepatic glucuronidation enzymes and deiodinases in the thyroid gland" (emphasis added, United States OSTP, 2023). Therefore, a thyroid-specific Hazard Index that excluded HFPO-DA and PFNA would underestimate the dose additivity concerns for thyroid effects from the total mixture.

Pennsylvania Municipal Authorities Association (Doc. #1832, SBC-045793)

[PMAA's specific comments on the Proposal are as follows:]

18. PMAA has concerns with and questions EPA's approach in the Proposal related to the use of the Hazard Index for certain PFAS chemicals. This is the first time that such a Hazard Index is used within the context of the Safe Drinking Water Act, which is a tool used to evaluate potential health risks from exposure to chemical mixtures. More time is needed to fully evaluate and analyze this approach, and PMAA recommends that this Hazard Index approach be deleted from the Proposal, pending further review and evaluation of the appropriateness of using it in the context of a Safe Drinking Water Act PFAS regulation.

Once again, PMAA appreciates the opportunity to submit comments on this most novel and complex Proposal.

Very truly yours,

HAMBURG, RUBIN, MULLIN, MAXWELL & LUPIN

STEVEN A. HANN

SAH:ll

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

The Chemours Company FC, LLC (Doc. #1845, SBC-046054)

C. EPA's Hazard Index for mixtures of PFAS compounds including HFPO-DA is scientifically flawed

EPA's proposal to use a Hazard Index ("HI") approach for regulating mixtures of PFHxS, HFPO-DA, PFNA, and PFBS not only is not authorized by the SDWA, as discussed above, but also is not scientifically sound. First, as summarized in the preceding subsections, the 10 ppt level for HFPO-DA developed by EPA and included in the HI is deeply flawed. Second, there is no scientific basis for EPA's aggregation of HFPO-DA with the other three compounds in the HI. As set forth in further detail in the supporting technical comments prepared by Dr. Chad Thompson and Dr. Melissa Heintz (Exhibit 1), the science does not support EPA's HI approach for several reasons, including:

• Occurrence data demonstrate that HFPO-DA is detected infrequently in drinking water across the United States and also is detected infrequently with other compounds in the HI. This limited occurrence of HFPO-DA and limited co- occurrence with the other HI compounds demonstrate that it is unsupported for EPA to regulate all of these compounds together as a group.

• Toxicological studies do not indicate that the compounds in the HI have additive effects. EPA's speculation about "dose additivity" for these compounds is wholly unsupported. The one study (Conley et al. 2022) that EPA cites purportedly in support of dose additivity for mixtures of PFAS compounds addressed only PFOA and PFOS, not the HI compounds.

• Further, EPA fails to cite several studies that found no support for dose additivity for mixtures of PFAS compounds.

• While there is no support for dose additivity in general for the HI compounds, there is also no support for any additivity or increased or cumulative risk at the specific levels EPA has set for each compound. In other words, EPA's summation of the HBWC levels for each compound in the HI is inappropriate. The HBWC level for each compound in the HI is based on calculations by EPA that include orders of magnitude of uncertainty factors for each compound that result in a level below which no adverse effect is expected. The HI then further multiplies those uncertainty factors by aggregating all the HBWC levels together, resulting in an unprecedented extremely and excessively conservative approach that goes well beyond an "adequate margin of safety."

• The HBWC levels for the compounds in the HI are based on different toxicological endpoints with different modes of action in different organs in different animal studies for the different

compounds, such that there is no toxicological similarity to support aggregating these disparate HBWC levels into the same HI.

• The compounds in the HI also differ significantly in terms of their chemical structures and properties and their potentials for bioaccumulation. Plainly, there is no scientific basis for similarity to support EPA's grouping these compounds all into one HI here.

Finally, EPA has grossly mischaracterized the recommendations of its Science Advisory Board ("SAB") regarding the HI approach. The SAB stated in general terms that the HI approach "is appropriate for initial screening of whether exposure to a mixture of PFAS poses a potential risk that should be further evaluated" and expressed its support for "dose additivity based on a common outcome."[FN31: U.S. EPA SAB, Review of EPA's Analyses to Support EPA's National Primary Drinking Water Rulemaking for PFAS. EPA-SAB-22-008 (2022).] The SAB did not endorse the HI approach for regulating mixtures of PFHxS, HFPO-DA, PFNA, and PFBS. [FN32: Id.] And, contrary to the SAB's recommendations, EPA has grouped these four compounds in the HI based on different toxicological outcomes for each compound, rather than a "common outcome."

In conclusion, for the reasons summarized above and discussed in the attached technical comments, EPA's aggregation of HFPO-DA with the other three compounds in the HI is arbitrary, capricious, and scientifically unsound.

EPA Response: Please see sections 4.3.1, 3.1.2, 3.2.2, 6.3, and 4.3.2 of the EPA response in this *Response to Comments* document.

In response to the comment that "EPA's summation of the HBWC levels for each compound in the HI is inappropriate," the EPA disagrees. The Hazard Index MCLG reflects both the measured amount of each of the four PFAS in a mixture and the toxicity (represented by the HBWC) of each of the four PFAS. The PFAS mixture Hazard Index is an approach to determine whether any mixture of two or more of these four PFAS in drinking water exceeds a level of health concern by first calculating the ratio of the measured concentration of each of the four PFAS to the toxicity (the HBWC) of each of the four PFAS. This results in the "HQ" for each of the four PFAS. The four HQs are added together to derive the Hazard Index , and doing so produces a Hazard Index that accounts for dose-additive concerns associated with these PFAS when present in mixtures (USEPA, 2024i; see also section 4.3.2 of this *Response to Comments* document). If the Hazard Index exceeds 1, then the hazard from the combined amounts of the four PFAS in drinking water exceeds a level of public health concern.

Prince William County Service Authority (Doc. #1609, SBC-042846)

EPA should not utilize the Hazard Index approach for PFNA, PFHxS, PFBS, and HFPO-DA.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Prince William County Service Authority (Doc. #1609, SBC-042832)

The proposal to use a Hazard Index calculation for PFNA, PFHxS, PFBS, and HFPO-DA is an approach that has never been used under the Safe Drinking Water Act. The approach combines compounds with different health endpoints. Utilities could exceed the HI even if each compound is below the limits of health impacts. Further, the HI approach will be challenging to communicate to the public. EPA should instead establish MCL's for these compounds using reference doses (RfDs) and human health toxicity assessments when they are available.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Nebraska Department of Environment and Energy (NDEE) (Doc. #1653, SBC-043207)

The proposed rule is not clear regarding whether the Health Based Water Criteria (HBWC) used to calculate the HI are set values as part of this rulemaking or if they are independent values that can potentially be lowered at a later date. If the later is the case, that would increase the weight of given sample results raising the HI. The Department suggests EPA clarify this in the final rule and explain how the HBWCs could change in the future as more data and information is gathered.

EPA Response: Please see sections 4.3.2 and 5 of the EPA response in this *Response to Comments* document.

New York State Department of Health (NYS DOH) (Doc. #1677, SBC-044963)

A further anomaly in the hazard index approach concerns the way the hazard quotients are calculated. Hazard quotients are traditionally calculated as a ratio of equivalent measures of exposure. In other words, the contaminant exposure (usually in mg/kg/day) is typically compared to an unadjusted reference dose. The hazard quotients in the proposed rule are analogously calculated using water concentrations, but the water concentration representing the exposure of interest is compared to a health-based water concentration that is adjusted by a 20% relative source contribution. This is a departure from the traditional hazard quotient calculation used in risk assessment, biases the calculation toward non-compliance, and may overestimate the level of noncancer risk.

EPA Response: Regarding the comment on the calculation of the Hazard Index in terms of water concentration, as described in the EPA's PFAS Mixtures Framework (USEPA, 2024i), the HQs and the Hazard Index are unitless, so in the Hazard Index formula (Equation 5-1 in PFAS Mixtures Framework), E and the RfV must be in the same units. For example, if E is the oral intake rate (mg/kg-day), then the RfV could be the RfD, which has the same units. Alternatively, the exposure metric can be a media-specific metric such as water concentration, and the toxicity reference value is best represented as an HBWC or MCLG (i.e., the level below which adverse effects are not anticipated to occur and allows for an adequate a margin of safety).

In this case, the HQ is calculated as the ratio of PFAS water concentration (in mass/volume) to a HBWC (also in mass/volume), resulting in a unitless value. The Hazard Index accounts for the combined effects of the different mixture components and compares the exposure level of each component to that component's corresponding HBWC, which is based on the most sensitive known adverse health outcome for that component. In this context, the HBWC is the level below which adverse health effects over a lifetime of exposure are not expected to occur, including for sensitive populations and life stages, and allows for an adequate margin of safety. This level also meets the definition of an MCLG, which is the level of a contaminant below which there are no known or anticipated adverse effects with an adequate margin of safety. Regarding the comment on the inclusion of RSC in the HBWC calculation, the RSC is part of the HBWC calculation and is applied to ensure that potential exposure sources beyond drinking water are considered (please see section 4.3.3 of this *Response to Comments* document). The EPA has applied the RSC to calculate health-protective water values under the Clean Water Act and the Safe Drinking Water Act for decades and disagrees that inclusion of the RSC "biases the calculation toward non-compliance, and may overestimate the level of noncancer risk."

3M Company (Doc. #1774, SBC-045678)

f. The Hazard Index Fails to Provide Regulatory Certainty

The unprecedented HI-MCL "standard" is not actually a fixed standard. Instead, the "standard" is based on an unlimited combination of detections of the four HI-MCL substances, all of which can be below their respective HBWC, and still be considered a violation of MCL. Similar results where all four substances are below their HBWCs can have different regulatory outcomes. EPA has not set a single MCL for the HI-PFAS. Instead, the proposed HI-MCL is actually thousands of fluid standards.

Such unpredictable and inconsistent regulatory outcomes raise a host of issues, including fundamental issues regarding fairness, equity, and regulatory certainty. There is no evidence in the Proposed Rule or supporting materials that EPA considered these issues before proposing the HI-MCL. That lack of reasoned consideration is the hallmark of arbitrary agency action.

EPA Response: The EPA disagrees that the Hazard Index does not provide regulatory certainty. The Hazard Index MCL regulatory limits are clear and certain. Please see sections 4.3.2 and 5 of the EPA response in this *Response to Comments* document.

Minnesota Pollution Control Agency (MPCA) (Doc. #1569, SBC-052823)

4) EPA requests comment on whether the HBWCs should instead be proposed as stand-alone MCLGs in addition to or in lieu of the mixture MCLGs.

MPCA response:

• MPCA supports setting the MCLG for these four PFAS as a mixture HI as the most health protective approach.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Water One – Water District No. 1 of Johnson County, Kansas (Doc. #1627, SBC-042327)

The Hazard Index (HI) concept is also new to drinking water regulations as it has typically only been used in the wastewater industry. It seems unlikely that appropriate Health Risk Assessments could have been performed and verified to support the numbers in the proposed regulation in such a short time span. Furthermore, the HI is a concern given there may be the instance where there is one compound that forces a violation when the other compounds assessed are in check. It simply does not have the same scientific level of scrutiny yet. It appears as though the EPA is entrenched with health advisory information and needs additional time to further develop the science behind the HI.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

The Chemours Company FC, LLC (Doc. #1845, SBC-046059)

2) The overall weight of the evidence does not support grouping these specific four PFAS.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document.

Association of State and Territorial Solid Waste Management Officials (ASTSWMO) (Doc. #1583, SBC-042396)

May 25, 2023

U.S. Environmental Protection Agency

EPA Docket Center

Mail Code 2822IT

1200 Pennsylvania Avenue, NW

Washington, DC 20460

RE: ASTSWMO Comments on U.S. EPA's Proposed PFAS National Priority Drinking Water Regulation; Docket ID No. EPA-HQ-OW-2022-0114

Dear Sir or Madam:

The Association of State and Territorial Solid Waste Management Officials (ASTSWMO) appreciates the opportunity to provide comments regarding the U.S. Environmental Protection Agency's (EPA) proposed Per- and polyfluoroalkyl substances (PFAS) National Primary

Drinking Water Regulation (NPDWR) Rulemaking. ASTSWMO is an association representing the waste management and remediation programs of the 50 States, five Territories, and the District of Columbia (States). Our membership includes State program experts from all States who manage State-run programs under both the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) and the Resource Conservation and Recovery Act (RCRA).

ASTSWMO commends the EPA for taking this important step to regulate perfluorooctanoic acid (PFOA), perfluorooctane sulfonic acid (PFOS), perfluorohexane sulfonic acid (PFHxS), hexafluoropropylene oxide dimer acid (HFPO–DA) and its ammonium salt (also known as GenX chemicals), perfluorononanoic acid (PFNA), perfluorobutane sulfonic acid (PFBS), and mixtures of these PFAS under the Safe Drinking Water Act (SDWA) and is pleased to offer comments on this proposed regulation.

ASTSWMO's PFAS Position Paper, drafted by the Association's Contaminants of Emerging Concern (CEC) Steering Committee, and updated and approved by our Board in November 2022, recommends that EPA evaluate classes of PFAS that have common characteristics, to more expeditiously designate PFAS compounds as CERCLA hazardous substances and RCRA hazardous constituents. However, the summary document (EPA-822-P-23-004) distributed for public comment on the combined Maximum Contaminant Level Goals (MCLGs) does not adequately explain why PFHxS, GenX chemicals, PFNA, and PFBS, four seemingly disparate PFAS, were selected. ASTSWMO recommends more careful consideration of PFAS functional groups, chain length, and toxic endpoints, and the use of a more-refined approach for the combined regulation of these chemicals.

EPA's promulgation of health-based MCLGs for the aforementioned PFAS compounds would advance federal and State efforts to compel responsible and potentially-responsible parties to investigate and remediate contamination nationwide, especially when private wells and public water supply systems are impacted. This is a critical step for impacted communities' access to financial resources for costly mitigation and cleanup.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. Regarding the EPA's rationale for regulation of PFHxS, HFPO-DA, PFNA, and PFBS, as required under the SDWA, there is available health effects, occurrence, and meaningful opportunity information for three PFAS (PFHxS, PFNA, and HFPO-DA) to meet the statutory criteria for regulation individually, and for four PFAS (PFHxS, PFNA, HFPO-DA, and PFBS) as a mixture (please see section 3 of this *Response to Comments* document and section III of the final rule preamble for the agency's evaluation of this information). Furthermore, the EPA disagrees that these four PFAS are disparate because they share similar characteristics; it is substantially likely that they co-occur; the same treatment technologies can be used for their removal; they are measured simultaneously using the same analytical methods; they have shared adverse health effects; and they have similar physical and chemical properties resulting in their environmental persistence.

HRSD (Doc. #1719, SBC-043540)

We see the following recommendations as productive and protective strategies that EPA can utilize:

Proceed with regulation for PFOA and PFOS for which occurrence and toxicity data are more robust

Though we cannot comment on the appropriateness of the specific MCLs for PFOA and PFOS, the general MCL development approach for these two contaminants appears to be data driven. EPA's approach to regulating the mixture of PFHxS, PFNA, PFBS and HFPO-DA, however, utilizes a Hazard Index (HI) approach that is novel in the context of SDWA regulation. This is being proposed without the benefit of occurrence data that will be generated under the Unregulated Contaminant Monitoring Rule (UCMR) 5.

EPA Response: Please see sections 4.3.2 and 6 of the EPA response in this *Response to Comments* document.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-052877)

b. CWUC is more supportive of EPA establishing individual MCLs, utilizing the HBWCs.

b. If EPA does move forward with the HI approach, it seems ineffective to include PFBS at a level of 2000 because that parameter won't even be included in the HI value unless it is very high (at least 200 ppt in the finished water), levels we assume most facilities don't see.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. As described in section III of the preamble, even though concentrations of PFBS are likely to be below its corresponding individual HRL when it occurs in a mixture, the record indicates that there is a substantial likelihood that it co-occurs with the regulated PFAS throughout PWSs nationwide. See section VI.C. of the preamble for further discussion. According to the 2023 Interagency PFAS Report to Congress (United States OSTP, 2023), PFBS has been shown to affect the following health domains: body weight, respiratory, cardiovascular, gastrointestinal, hematological, musculoskeletal, hepatic, renal, ocular, endocrine, immunological, neurological, reproductive, and developmental. Thus, including PFBS as a mixture component represents a meaningful opportunity to reduce PFBS' contributions to the overall hazard of PFAS mixtures and resulting dose additive health concerns. This is particularly relevant where the exposure levels of the other three PFAS in the mixture are also below their respective HRLs but when the hazard contributions of each mixture component are summed, the total exceeds the mixture HRL. In this scenario, the inclusion of PFBS allows for a more accurate picture of the overall hazard of the mixture so that PFBS can be reduced along with associated dose additive health concerns. In short, hazard would be underestimated if PFBS was not included in the regulated mixture. The EPA also considered potential situations where PFHxS, PFNA, or HFPO-DA exceed one or more of their corresponding HRLs and co-occur with PFBS below its corresponding HRL. Although in this case, the exceedance of the mixture

HRL is driven by a PFAS other than PFBS, PFBS is contributing to the overall hazard of the mixture and resulting dose additive health concerns. Including PFBS in the regulated mixture offers a meaningful opportunity to reduce dose additive health concerns because, when PFBS and other Hazard Index PFAS are present, PWSs will be able to better design and optimize their treatment systems to remove PFBS and any other co-occurring Hazard Index PFAS. This optimization will be even more effective with information about the presence and measured concentrations of PFBS in source waters.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-052879)

d. If EPA does move forward with the HI approach, they should consider an HI of 1.3. This would be the value obtained for having three of the parameters (not including PFBS because it doesn't affect the HI) at the PQL of 4.0 ppt. The trigger level should be set at 0.6, which would be a value obtained of 2.0 ppt for the three parameters. Values below two (and therefore a lower trigger level) are not accurate and should not be used for compliance.

EPA Response: Please see section 4.3.2 of the EPA response in this *Response to Comments* document. The EPA disagrees that any number other than 1 is appropriate for the Hazard Index MCLG. A Hazard Index greater than 1 is generally regarded as an indicator of potential adverse health risks associated with a specific level of exposure to the mixture; a Hazard Index less than or equal to 1 is generally regarded as not being associated with any appreciable risk (USEPA, 1986; USEPA, 1991c; USEPA, 2000b). Thus, in the case of this drinking water rule, a Hazard Index greater than 1 indicates that occurrence of one or more of these four component PFAS in a mixture in drinking water exceeds the health protective level(s) (i.e., HBWC(s)), indicating potential health risks. Additionally, the commenter's suggestion of a Hazard Index of 1.3 would round to 1 when using one significant digit so there would be no practical difference (please see section 4.3.4 of this *Response to Comments* document). For the EPA response to the comment on trigger levels, see section 8 of this *Response to Comments* document.

4.3.3 Derivation of the Four HRLs and HBWCs in the Hazard Index MCLG

The agency developed HRLs for PFHxS, PFNA, HFPO-DA, and PFBS as part of its effort to identify the adverse effects each contaminant may have on the health of persons. In this instance, the EPA identified the HRL as the level below which adverse health effects over a lifetime of exposure are not expected to occur, including for sensitive populations and life stages, and allowing an adequate margin of safety. The HRLs are also used as HBWCs in the calculation of the Hazard Index MCLG. This section summarizes public comments and the EPA responses related to the calculation of the HRLs and the HBWCs applied in the Hazard Index MCLG calculation.

Summary of Major Public Comments and EPA Responses (General)

Some commenters supported the EPA's derivation of the four HRLs/HBWCs for PFHxS, PFNA, HFPO-DA and PFBS. Many commenters expressed support for the EPA's derivation of HRLs/HBWCs based on the best available peer-reviewed science, specifically the use of the final, most recently published ATSDR minimal risk levels for PFHxS and PFNA as chronic toxicity reference values. Other commenters criticized the EPA for using ATSDR minimal risk levels and stated that they are inappropriate for SDWA rulemaking.

Some commenters questioned the EPA's external peer-review process for the four underlying final toxicity assessments used to calculate the HRLs/HBWCs and for the HBWCs themselves. Some commenters noted that the EPA does not yet have completed IRIS assessments for PFHxS and PFNA, questioning the EPA's use of non-EPA assessments.

Some commenters asserted that the human health toxicity reference values (EPA RfDs, ATSDR minimal risk levels) upon which the HRLs/HBWCs are based have too much uncertainty (e.g., inappropriately apply a composite uncertainty factor (UF) of 3,000) and are therefore inadequate to support a SDWA regulatory determination.

Some commenters opposed the EPA's application of a 20 percent RSC in the HRL/HBWC calculations and stated that it was a "conservative default" approach not supported by available information and that adequate exposure data exist to justify an RSC other than 20 percent (although commenters did not offer a suggested alternative RSC).

Some commenters disagreed with the DWI-BWs that the EPA used to calculate the HRLs/HBWCs and thought the selected DWI-BWs were too high (overly health protective). One commenter stated that the DWI-BW used in the calculation of the HRL/HBWC for HFPO-DA is inappropriate and that the EPA should have used a DWI-BW for general population adults instead of for lactating women. Other commenters urged the EPA to consider infants as a sensitive life stage for PFHxS, PFNA, and PFBS and use the DWI-BW for infants to calculate the HRLs/HBWCs.

Some commenters offered critical comments on the HRLs/HBWCs for PFHxS, PFNA, HFPO-DA, and PFBS and raised technical and process concerns with the underlying human health assessments. Some commenters questioned the EPA's reliance on animal data and its relevance to humans; for example, some commenters claimed that the liver effects observed in rats after exposure to HFPO-DA (the basis for the RfD for HFPO-DA) are not relevant to humans.

The EPA response to these issues as well as others expressed by individual commenters are described in further detail below.

Use of ATSDR Minimal Risk Levels for PFHxS and PFNA. The EPA disagrees with commenters who assert that it is inappropriate to use ATSDR minimal risk levels as toxicity reference values. The EPA finds that the ATSDR minimal risk levels for PFHxS and PFNA currently represent the best available, peer-reviewed science for these chemicals. SDWA specifies that an agency action that is based on science must rely on "the best available, peer-

reviewed science and supporting studies conducted in accordance with sound and objective scientific practices." At this time, the 2021 ATSDR *Toxicological Profile for Perfluoroalkyls*, which covers 10 PFAS including PFHxS and PFNA, represents the best available peer-reviewed scientific information on the human health effects of PFHxS and PFNA. ATSDR minimal risk levels for PFHxS and PFNA are appropriate for use under SDWA because ATSDR uses scientifically credible approaches, its work is internally and externally peer-reviewed and undergoes public comment, and its work represents the current best available science for these two chemicals. The 2021 ATSDR *Toxicological Profile for Perfluoroalkyls* underwent intra- and interagency review and subsequent external peer review by seven experts with knowledge of toxicology, chemistry, and/or health effects.

The agency acknowledges that ATSDR minimal risk levels and EPA RfDs are not identical. The two agencies sometimes develop toxicity values for different exposure durations (e.g., intermediate, chronic) and/or apply different uncertainty/modifying factors to reflect data limitations. Additionally, ATSDR minimal risk levels and EPA RfDs are developed for different purposes: ATSDR minimal risk levels are intended to serve as screening levels and are used to identify contaminants and potential health effects that may be of concern at contaminated sites, whereas EPA RfDs are used to support regulatory and nonregulatory actions, limits, and recommendations in various environmental media. However, an oral minimal risk level and an oral RfD both represent the level of daily oral human exposure to a hazardous substance below which adverse health effects are not anticipated to occur. The EPA has routinely used and continues to use ATSDR minimal risk levels in human health assessments when they represent the best available science—for example, in the context of Clean Air Act section 112(f)(2) risk assessments in support of setting national emission standards for Hazardous Air Pollutants (HAPs), developing Clean Water Act ambient water quality criteria, evaluating contaminants for the CCL, and site evaluations under the Resource Conservation and Recovery Act (RCRA) and CERCLA.

The EPA is not required under SDWA to exclusively use EPA assessments to support an NPDWR, and in fact, SDWA's clear direction in Section 1412(b)(3)(A)(i) is to use the best *available*, peer- reviewed science when developing NPDWRs (emphasis added). Final EPA assessments for PFHxS and PFNA are under development but are not currently available; final, peer-reviewed ATSDR assessments are available. The statute recognizes that the EPA may act in the face of imperfect information. It also provides a mechanism for the EPA to update standards as more information becomes available. For the PFAS covered by this rule, the EPA concluded that the state of the science and information has sufficiently advanced to the point to satisfy the statutory requirements and fulfill SDWA's purpose to protect public health by addressing contaminants in the nation's PWSs.

Peer Review. The EPA disagrees with comments that peer review was inadequate. The EPA notes that all four toxicity assessments underlying the HRL/HBWC calculations (i.e., the EPA human health toxicity assessments for HFPO-DA and PFBS (USEPA, 2021d; USEPA, 2021b) and the ATSDR toxicity assessments of PFNA and PFHxS (ATSDR, 2021)) underwent rigorous,

external peer review (ATSDR, 2021; USEPA, 2021d; USEPA, 2021e). The EPA is not required under SDWA to exclusively use EPA assessments to support an NPDWR, and in fact, SDWA's clear direction in Section 1412(b)(3)(A)(i) is to use the best available, peer-reviewed science when developing NPDWRs (emphasis added). Final EPA assessments for PFHxS and PFNA are not currently available; final, peer-reviewed ATSDR assessments are available.

Uncertainty. Some commenters asserted that the human health toxicity reference values (EPA RfDs, ATSDR minimal risk levels) upon which the HRLs/HBWCs are based have too much uncertainty (e.g., inappropriately apply a composite uncertainty factor (UF) of 3,000) and are therefore inadequate to support a SDWA regulatory determination. The EPA disagrees with these comments. The HRLs/HBWCs are data-driven values based on RfDs that incorporate UFs based on the EPA guidance and guidelines, and thus represent the levels below which adverse health effects are not expected to occur over a lifetime. According to the EPA guidelines and longstanding practices (USEPA, 2002a; USEPA, 2022a), UFs reflect the limitations of the data across the five areas used in current EPA human health risk assessment development: (1) human interindividual variability (UF_H); (2) extrapolation from animal to human (UF_A); (3) subchronic-to-chronic duration extrapolation (UF_S); (4) lowest-observed-adverse-effect level-to-no-observed-adverse-effect level (LOAEL-to-NOAEL) extrapolation (UF_L); and (5) database uncertainty (UF_D). In minimal risk level development, ATSDR also applies uncertainty factors as appropriate to address areas of uncertainty, with the exception of subchronic-to-chronic duration extrapolation (ATSDR, 2021). For the ATSDR minimal risk levels on which the HRLs/HBWCs for PFNA and PFHxS are based, ATSDR utilized UF_Hs, UF_As, and what ATSDR calls a modifying factor to address database deficiencies (equivalent to the EPA's UF_D) (ATSDR, 2021). The EPA carefully reviewed ATSDR's application of uncertainty and modifying factors for PFNA and PFHxS and applied additional uncertainty factors as warranted per the EPA guidelines. Specifically, the EPA applied an additional UF (UF_S) for PFHxS to extrapolate from subchronic to chronic duration per agency guidelines (USEPA, 2002a) and standard practice because the critical effect was not observed during a developmental lifestage (i.e., the effect was in parental male rats). A chronic toxicity reference value (i.e., RfD, minimal risk level) represents the daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime; the EPA is using chronic toxicity reference values to derive individual MCLGs (for HFPO-DA, PFNA, and PFHxS) and HBWCs for the PFAS mixture MCLG to ensure that each MCLG is set at a level at or below which no known or anticipated adverse effects on human health occur and allowing an adequate margin of safety. The MCLG "incorporates a margin of safety to reflect scientific uncertainty and, in some cases, the particular susceptibility of some groups (e.g., children) within the general population." S. Rep. No. 169, 104th Cong., 1st Sess. (1995) at 3. The EPA guidelines indicate that the composite (total) UF may be equal to or below 3,000; composite UFs greater than that represent "excessive uncertainty" (USEPA, 2002a; USEPA, 2022a). In the case of this final NPDWR, a composite UF of 3,000 was appropriately applied to derive toxicity reference values used to develop HRLs/HBWCs for two of the four PFAS (HFPO-DA and PFHxS) following peer-reviewed agency guidance and longstanding practice (see USEPA (2024h) for complete

discussion of UF application for all four PFAS). The EPA has previously developed an MCLG for a chemical that had a composite UF of 3,000 applied to derive a toxicity reference value (e.g., thallium [USEPA, 1992]). Further, a composite uncertainty factor of 3,000 has been applied in the derivation of oral RfDs for several chemicals that have been evaluated within the EPA's IRIS program (e.g., fluorene, cis- and trans-1,2-dichloroethylene, 2,4-dimethylphenol; please see the EPA's IRIS program website [https://www.epa.gov/iris] for further information).

With respect to the use of animal studies in general, SDWA requires that to the degree that the EPA's action is based on science, the EPA must use "the best available, peer reviewed science" and "data collected by accepted methods or best available methods." Additionally, as noted in the EPA's *Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a) and *A Review of the Reference Dose and Reference Concentration Process* (USEPA, 2002a), animal studies can provide the basis for toxicity reference values when adequate human studies are not available. The HBWCs/MCLGs are based on the best available science and data collected by accepted methods (see section III in the preamble and USEPA, 2024h). Specifically, peer-reviewed, publicly available toxicity assessments are available for HFPO-DA (USEPA, 2021e), PFBS (USEPA, 2021d), PFNA (ATSDR, 2021), and PFHxS (ATSDR, 2021) that provide the oral toxicity reference values (i.e., RfDs or minimal risk levels) used to calculate the HBWCs/MCLGs; the EPA selected the corresponding DWI-BW for the relevant sensitive population or life stage from the Exposure Factors Handbook (USEPA, 2019) based on the best available, peer-reviewed science from publicly available, peer-reviewed studies taking into account the relevant sensitive population(s) or life stage(s); and the RSCs are based on the best available, peer-reviewed science or best available methods taking into account the relevant sensitive population(s) or life stage(s) (USEPA, 2000c).

Relative Source Contribution (RSC). The EPA disagrees with comments that the RSCs derived for one or more of the four PFAS are inappropriate. The EPA applies an RSC to account for potential aggregate risk from exposure routes and exposure pathways other than oral ingestion of drinking water to ensure that an individual's total exposure to a contaminant does not exceed the daily exposure associated with toxicity (i.e., threshold level or reference dose). Application of the RSC in this context is consistent with EPA methods (USEPA, 2000c) and long-standing EPA practice for establishing drinking water MCLGs and NPDWRs (e.g., see USEPA, 1989; USEPA, 2004; USEPA, 2010). The RSC represents the proportion of an individual's total exposure to a contaminant that is attributed to drinking water ingestion (directly or indirectly in beverages like coffee, tea, or soup, as well as from dietary items prepared with drinking water) relative to other exposure pathways. The remainder of the exposure equal to the RfD (or minimal risk level) is allocated to other potential exposure sources (USEPA, 2000c). The purpose of the RSC is to ensure that the level of a contaminant (e.g., MCLG) in drinking water, when combined with other identified potential sources of exposure for the population of concern, will not result in total exposures that exceed the RfD (or minimal risk level) (USEPA, 2000c). This ensures that the MCLG under SDWA meets the statutory requirement that it is a level of a contaminant in drinking water at or below which no known or anticipated adverse effects on human health occur

and allowing an adequate margin of safety. The EPA is only regulating certain PFAS in drinking water consistent with the definition of contaminant in SDWA section 1401(6).

To determine the RSCs for the four HRLs/HBWCs, the agency assessed the available scientific literature on potential sources of human exposure other than drinking water. The EPA conducted literature searches and reviews for each of the four PFAS to identify potential sources of exposure and physicochemical properties that may influence occurrence in environmental media (Deluca et al., 2022; USEPA, 2024h). Considering this exposure information, the EPA followed its longstanding, peer-reviewed Exposure Decision Tree Approach in EPA's Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (USEPA, 2000c) to determine the RSC for each PFAS. As discussed by the EPA in the Hazard Index MCLG document (USEPA, 2024h), the EPA carefully evaluated studies that included information on potential exposure to these four PFAS (PFHxS, PFNA, HFPO-DA, and PFBS) via sources other than drinking water, such as food, soil, sediment, and air. For each of the four PFAS, the findings indicated that there are significant known or potential uses/sources of exposure beyond drinking water ingestion (e.g., food, indoor dust) (Box 6 in the EPA Exposure Tree; USEPA, 2000c), but that data are insufficient to allow for quantitative characterization of the different exposure sources (Box 8A in USEPA, 2000c). The EPA's Exposure Decision Tree approach states that when there are insufficient environmental and/or exposure data to permit quantitative derivation of the RSC, the recommended RSC for the general population is 20 percent (Box 8B in USEPA, 2000c). This means that 20 percent of the exposure equal to the RfD is allocated to drinking water, and the remaining 80 percent is attributed to all other potential exposure sources.

Drinking Water Intake (DWI-BW). The EPA disagrees with comments that alternate DWI-BWs should be used for HBWC calculations for one or more of the four PFAS. Some commenters disagreed with the DWI-BWs that the EPA used to calculate the HRLs/HBWCs and thought the selected DWI-BWs were too high (overly health protective).

Other commenters urged the EPA to use the DWI-BW for infants to calculate the HRLs/HBWCs. The EPA disagrees with this comment. The EPA's approach to DWI-BW selection includes a step to identify the sensitive population(s) or life stage(s) (i.e., those that may be more susceptible or sensitive to a chemical exposure) by considering the available data for the contaminant, including the adverse health effects observed in the toxicity study on which the RfD/minimal risk level was based (known as the critical effect within the critical or principal study). Although data gaps can complicate identification of the most sensitive population (e.g., not all windows or life stages of exposure and/or health outcomes may have been assessed in available studies), the critical effect and point of departure (POD) that form the basis for the RfD (or minimal risk level) can provide some information about sensitive populations because the critical effect is typically observed at the lowest tested dose among the available data. Evaluation of the critical study, including the exposure window, may identify a sensitive population or life stage (e.g., pregnant women, formula-fed infants, lactating women). In such cases, the EPA can select the corresponding DWI-BW for that sensitive population or life stage from the Exposure Factors Handbook (USEPA, 2019a). DWI-BWs in the Exposure Factors Handbook are based on

information from publicly available, peer-reviewed studies, and were updated in 2019. In the absence of information indicating a sensitive population or life stage, the DWI-BW corresponding to the general population may be selected. Following this approach, the EPA selected appropriate DWI-BWs for each of the four PFAS included in the Hazard Index MCLG (see USEPA, 2024h). The EPA did consider infants as a sensitive life stage for all four PFAS; however, the agency did not select the infant DWI-BW because the exposure intervals of the critical studies supporting the chronic toxicity reference values did not correspond to infants. Instead, the exposure intervals were relevant to other sensitive target populations (i.e., lactating women or women of childbearing age) or the general population.

Another commenter suggested that DWI-BW should be identified from evaluation of the database as a whole, rather than solely based on the critical study for a particular PFAS, to better protect sensitive subpopulations in light of data gaps. The EPA disagrees with this suggested approach because the Agency has already taken into account data gaps through application of uncertainty factors, including a database uncertainty factor (UF_D). Each of the chronic toxicity reference values for the four PFAS included in the Hazard Index take into account the strength of the database as a whole: the HFPO-DA and PFBS RfDs each include a UF_D of 10, and the PFNA and PFHxS minimal risk levels each include a modifying factor (MF) of 10 for database deficiencies. (See also the EPA response to comment above, under "Uncertainty.") As described above, the EPA follows a data-driven approach to select an appropriate DWI-BW based on the exposure window associated with the critical effect from the critical or principal study.

Comments Specifically on PFNA. Some commenters questioned the human relevance of developmental effects observed in PFNA animal studies (i.e., decreased body weight gain, delayed eye opening, delayed sexual maturation) used to derive the ATSDR minimal risk level and the EPA's PFNA HRL/HBWC/MCLG. The EPA disagrees with this comment. At this time, the 2021 ATSDR Toxicological Profile for Perfluoroalkyls represents the best available peer-reviewed scientific information regarding the human health effects of PFNA. In addition, according to the March 2023 *Interagency PFAS Report to Congress*, PFNA is documented to affect the developmental health domain (United States OSTP, 2023), and a recently published meta-analysis (Wright et al., 2023) specifically supports decreases in BWT as an effect of PFNA exposure in humans. Published studies have shown that PFNA exposure results in statistically significant, dose-responsive developmental effects, including reduced fetal/pup bodyweight, reduced fetal/pup survival, changes in fetal/pup liver gene expression, increased fetal/pup liver weight, and delayed onset of puberty. Also, the EPA's 1991 *Guidelines for Developmental Toxicity Risk Assessment* (USEPA, 1991d; pp. vii-ix and pp. 1-2) states that, in the absence of clear evidence to the contrary, developmental effects observed in experimental animals are interpreted as relevant to humans.

Comments Specifically on PFBS. A few commenters suggested that the EPA lower the HRL/HBWC for PFBS to account for thyroid hormone disruption during early development and cited the Washington State Action Level for PFBS, which is 345 ng/L. Washington State used the same RfD (3E-04 mg/kg-d) but a higher DWI-BW to develop its Action Level as compared to

the EPA's HRL/HBWC (Washington State used the 95th percentile DWI-BW of 0.174 L/kg/day for infants, whereas the EPA selected the 90th percentile DWI-BW of 0.0354 L/kg/day for women of child-bearing age). The EPA disagrees that the infant DWI-BW is more appropriate for HRL/HBWC calculation. The EPA selected the thyroid hormone outcome (decreased serum total thyroxine in newborn mice seen in a developmental toxicity study) as the critical effect in its PFBS human health toxicity assessment (USEPA, 2021d). Notably, the RfD derived from this critical effect included application of a 10X UF to account for lifestage-specific susceptibility (UF_H). To select a DWI-BW for use in deriving the HRL/HBWC for PFBS, the EPA followed its established approach of considering the PFBS exposure interval used in the developmental toxicity study in mice that was the basis for chronic RfD derivation. In this study, pregnant mice were exposed throughout gestation, which is relevant to two human adult life stages: women of child-bearing age who may be or become pregnant, and pregnant women and their developing embryos or fetuses (Table 3-63 in USEPA, 2019a). To be clear, the critical study exposed mice to PFBS only during pregnancy and not during postnatal development; newborn mice in early postnatal development, which would correspond to the human infancy life stage, were not exposed to PFBS. Of the two relevant adult stages, the EPA selected the 90th percentile DWI-BW for women of child-bearing age (0.0354 L/kg/day) to derive the HRL/HBWC for PFBS because it is the higher of the two, and therefore more health-protective. Please see additional information related to DWI-BW selection above.

Other commenters stated that the EPA's human health toxicity assessment for PFBS is overly conservative, uncertain, and that the confidence in the chronic RfD is low. The EPA disagrees with these comments. Confidence in the critical study (Feng et al., 2017) and corresponding critical effect in newborn mice was rated by the EPA as 'High;' this rating was a result of systematic study evaluation and risk of bias analysis by a team of EPA experts. The Feng et al. (2017) study, the critical effect of thyroid hormone disruption in offspring, dose-response assessment, and corresponding RfD were subjected to extensive internal EPA, interagency, and public/external peer review. While confidence in the critical study was rated 'High,' the 'Low' confidence rating for the PFBS chronic RfD was in part a result of the lack of a chronic exposure duration study in any mammalian species; this lack of a chronic duration study was one of the considerations that resulted in the EPA applying a UF of 10 to account for database limitations (UF_D). Additional database considerations that warranted a 'Low' confidence ranking for the PFBS RfD included the lack of studies that evaluated neurodevelopmental, immunological, or mammary gland effects. Further, available toxicokinetic studies are limited (e.g., one mouse toxicokinetic study) and toxicokinetic data do not exist for PFBS at all life stages, including neonates, infants, and children. Lastly, studies are not available to estimate the relative cross-species sensitivity in toxicodynamics (e.g., thyroid signaling) between mice and humans. Based on the EPA's human health assessment practices, the lowest confidence rating across the areas of consideration (e.g., existent hazard/dose-response database) is assigned to the corresponding derived reference value (e.g., RfD). Thus, the EPA has high confidence in the critical study (Feng et al., 2017) and critical effect/thyroid endpoint, but the database is relatively limited. Although the PFBS RfD was based on best available peer-reviewed science, there is uncertainty as to the

hazard profile associated with PFBS after prolonged (e.g., lifetime) oral exposure. In the toxicity assessment for PFBS (USEPA, 2021d), the EPA noted data gaps in specific health effects domains, as is standard practice. Toxicity assessments for most chemicals identify data gaps; the issue of uncertainty due to toxicological study data gaps is not unique to PFBS. Data gaps are considered when selecting the UF_D because they indicate the potential for exposure to lead to adverse health effects at doses lower than the POD derived from the assessment's critical study. There is a potential that effects with greater dose-response sensitivity (i.e., occurring at lower daily oral exposures) might be discovered from a chronic duration exposure study. Due to this uncertainty, the EPA applied a UF_D of 10.

A few commenters questioned the human significance of thyroid hormone changes (T3, T4 levels) in newborn rodents to PFBS human risk assessment, with one commenter stating that the thyroid effects could have been secondary to liver effects. The EPA disagrees with this comment. As noted in the human health toxicity assessment for PFBS (USEPA, 2021d), PFBS-induced perturbation of the thyroid was consistently observed across two species, sexes, life stages, and exposure durations in two independent, high-confidence studies, and these perturbations involved a coherent pattern of hormonal changes. The toxicity assessment for PFBS (USEPA, 2021d) concluded that these changes in rodents are adverse and human-relevant, and appropriate for RfD derivation. Additionally, as it specifically pertains to the study/effect used as the basis of the PFBS RfD (USEPA, 2021d), a critical nuance is that T4 decrements occur during an early lifestage (e.g., in utero). So, while it is agreed that there are some key differences in thyroid hormone homeostasis between *adult* humans and rodents (e.g., carrier protein profile), these differences are effectively negated in a state of pregnancy. The placentas of both humans and rodents serve as a gatekeeper for transit of highly controlled levels of T4 to support proper TH-dependent tissue development across trimesters. That is, rodents and humans are more alike during pregnancy as compared to non-pregnant adults across species. So, the level of T4 available to offspring during in utero development is critical to proper development. This is indeed an adverse health scenario (i.e., too little T4/T3 especially in early pregnancy can have profound impacts on health of offspring). One of the most critical health outcomes consistently associated with decreased T4 (and T3) during in utero development is neurocognitive deficits. Further, as noted in the toxicity assessment for PFBS (USEPA, 2021d), "Although there are some differences in hypothalamic-pituitary-thyroid (HPT) regulation across species (e.g., serum hormone-binding proteins, hormone turnover rates, and timing of *in utero* thyroid development), rodents are generally considered to be a good model for evaluating the potential for thyroid effects of chemicals in humans (Zoeller et al., 2007). For more details pertaining to HPT dynamics and the similarities and differences associated with thyroid hormone economy between rodents and humans, please refer to *A Literature Review of the Current State of the Science Regarding Species Differences in the Control of, and Response to, Thyroid Hormone Perturbations. Part 1: A Human Health Perspective* (Regulatory Science Associates, 2019). The pattern of decreased thyroid hormones in the absence of a coordinated reflex increase in TSH and commensurate alterations in thyroid tissue weight and/or histology, observed in PFBS studies [e.g., Feng et al. (2017)], is consistent with the human clinical condition referred to as

"hypothyroxinemia," which is commonly associated with pregnancy in humans." For a full discussion of the human relevance of the thyroid hormone changes seen in rodents, please see USEPA (2021d).

One commenter questioned the EPA's approach to estimating the human equivalent dose (HED) from the animal data using toxicokinetic (TK) data rather than using default body-weight scaling and suggested that the default allometric approach is more appropriate for estimating an HED. The EPA disagrees with this comment. In human health risk assessment practice, the EPA considers a hierarchical approach to cross-species dosimetric scaling consistent with technical guidance to calculate HEDs (USEPA, 2011; see pp. X-XI of the Executive Summary in '*Recommended Use of Body Weight$^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose*'). The preferred approach is physiologically based toxicokinetic (PBTK) modeling; however, there are rarely sufficient chemical-specific data to properly parameterize such a model. In the absence of a PBTK model, the EPA considers an intermediate approach in which chemical-specific data across species, such as clearance or plasma half-life, are used to calculate a DAF (USEPA, 2011). If chemical-specific TK data are not available, only then is a default approach used wherein allometric scaling, based on body weight raised to the ¾ power, is used to calculate a DAF. The human health toxicity assessment for PFBS invoked the intermediate approach, consistent with guidance, as TK data were available for humans and rodents.

Comments Specifically on PFHxS. Some commenters noted a typographical error in the HRL/HBWC calculation for PFHxS which was reported as 9.0 ng/L in the proposal. The agency has corrected the value in this NPDWR and within the requirements under 141 CFR Subpart Z. The correct HRL/HBWC for PFHxS is 10 ng/L.

Two commenters questioned the human relevance of thyroid effects (i.e., changes in tissue structure (e.g., enlarged cells; increased numbers of cells) in the thyroids of adult male rats) observed in the critical study used to derive the ATSDR minimal risk level and the EPA's PFHxS HRL/HBWC/MCLG because, as noted in the ATSDR *Toxicological Profile for Perfluoroalkyls*, this observed effect may have been secondary to liver toxicity and, therefore, the commenters state that its significance is unclear. The EPA disagrees with this comment. SDWA requires that to the degree that the EPA's action is based on science, the EPA use "the best available, peer reviewed science" to inform decision making on drinking water regulations. Although there is some uncertainty regarding the selection of thyroid alterations as the critical effect (as the ATSDR toxicological profile notes), at this time, the 2021 ATSDR toxicological profile represents the best available peer reviewed scientific information regarding the human health effects of PFHxS. As the most sensitive known effect as supported by the weight of the evidence, the thyroid effect was appropriately selected by ATSDR as the critical effect. Additionally, published studies in rats have shown that PFHxS exposure results in other thyroid effects, including decreases in thyroid hormone (primarily T4) levels in serum (NTP, 2018a; Ramhøj et al., 2018). Similarly, peer-reviewed final EPA assessments of other PFAS, including PFBS (USEPA, 2021d) and perfluorobutanoic acid (PFBA) (USEPA, 2021h), have concluded that these changes in rodents are adverse and human-relevant, and appropriate for RfD derivation.

Furthermore, it is appropriate to use other health protective (toxicity) values developed by other authoritative governmental agencies, including ATSDR minimal risk levels, if available, as these agencies use scientifically credible approaches and their work is peer-reviewed (the ATSDR toxicological profile underwent intra- and interagency review and external peer review by seven experts with knowledge of toxicology, chemistry, and/or health effects). The ATSDR minimal risk levels reflect the best available, peer-reviewed science.

Furthermore, the EPA's draft *IRIS Toxicological Review of Perfluorohexanesulfonic Acid (PFHxS) and Related Salts (Public Comment and External Review Draft)* (USEPA, 2023h), which is in the public domain, preliminarily provides confirmatory evidence that PFHxS significantly affects human development (emphasis added): "Overall, the available evidence indicates that *PFHxS exposure is likely to cause thyroid and developmental immune effects in humans*, given sufficient exposure conditions. For thyroid effects, the primary supporting evidence for this hazard conclusion included evidence of decreased thyroid hormone levels, abnormal histopathology results, and changes in organ weight in experimental animals. For immune effects, the primary supporting evidence included decreased antibody responses to vaccination against tetanus or diphtheria in children." Although the EPA did not rely on this draft IRIS toxicological review for PFHxS in this rulemaking, the draft is available to the public and offers confirmation that PFHxS elicits developmental effects in humans.

Comments Specifically on HFPO-DA. A few commenters submitted critical comments related to the adverse health effects associated with exposure to HFPO-DA and how these health effects are quantified to derive the RfD in the human health toxicity assessment for HFPO-DA (USEPA, 2021e), which was used to calculate the HRL/HBWC/MCLG. Commenters claimed that the RfD for HFPO-DA is not scientifically sound, and cited one or more of the following reasons why: 1) the selected critical effect (constellation of liver lesions) includes different liver effects that were not consistently observed across male and female mice and were not necessarily all adverse; 2) the hepatic effects in mice (the selected critical effect) are mediated by a rodent-specific MOA, peroxisome proliferator-activated receptor alpha (PPARα) activation, and therefore not relevant to humans; 3) the EPA incorporated results of a pathology working group which misapplied diagnostic criteria classifying apoptotic and necrotic lesions; and 4) the EPA misapplied uncertainty factors (UFs) (i.e., the subchronic to chronic UF and database UF), resulting in the maximum possible UF of 3,000 according to agency guidance (USEPA, 2002a; USEPA, 2022a). Another commenter thought that the interspecies UF should be further increased. Also, some commenters stated that the EPA did not properly consider all available epidemiological data, and one commenter stated that the DWI-BW used in the calculation of the HRL/HBWC for HFPO-DA is inappropriate. These comments are addressed below.

Overall, the EPA disagrees with the commenters and maintains that the final published peer-reviewed human health toxicity assessment that derived the RfD for HFPO-DA is appropriate and sound, reflects the best available peer-reviewed science, and is consistent with agency guidance, guidelines, and best practices for human health risk assessment. Notably, the EPA sought external peer review of the toxicity assessment *twice* (USEPA, 2018b; USEPA, 2021i),

released the draft toxicity assessment for public comment and provided responses to public comment (USEPA, 2021j), and engaged a seven-member pathology working group at the National Institutes of Health—an entirely separate and independent organization—to re-analyze pathology slides from two critical studies (USEPA, 2021e, Appendix D), all of which supported the EPA's conclusions in the toxicity assessment, including the RfD derivation.

Regarding critical effect selection: the EPA's approach to critical effect selection for the RfD derivation considers a range of factors, including doses at which effects are observed, biological variability (which can produce differences in effects observed between sexes), and relevance of the effect(s) seen in animals to human health. The EPA engaged a pathology working group within the National Toxicology Program (NTP) at the National Institutes of Health to perform an independent analysis of the liver tissue slides from the critical study and the pathology working group determined that the tissue slides demonstrated a range of adverse effects and that the constellation of liver effects caused by HFPO-DA exposure, which included cytoplasmic alteration, apoptosis, single cell necrosis, and focal necrosis, constitutes an adverse liver effect in these studies (USEPA, 2021e, Appendix D). The EPA evaluated the results of the pathology working group and determined that the effects were relevant to humans according to peer-reviewed, best available science (e.g., Hall et al., 2012). Additionally, the EPA convened a second independent peer-review panel of human health risk assessment experts to review the EPA's work on HFPO-DA, including critical effect selection. The panel unanimously agreed with the selection of the constellation of liver lesions as the critical effect, the adversity of this effect, and its relevance to humans (USEPA, 2021i).

The commenters' assertion that the hepatic effects observed in mice are not relevant to humans because they are PPARα-mediated is unsupported. Commenters claim that one specific effect—apoptosis—can be PPARα-mediated in rodents (a pathway that some data suggest may be of limited or no relevance to humans). However, in supporting studies cited by commenters, a decrease in apoptosis is associated with a PPARα-mediated MOA, with Corton et al. (2018) stating, "[t]he data indicate that a physiological function of PPARα activation is to increase hepatocyte growth through an increase in hepatocyte proliferation or a decrease in apoptosis or a combination of both effects" while HFPO-DA is associated with increased apoptosis (USEPA, 2021e). Therefore, the commenter's claim that apoptosis is associated with the known PPARα-mediated MOA is unsupported. Despite this, the critical study selected by the EPA, and indeed other studies as well, reported not only apoptosis but also other liver effects such as necrosis that are not associated with a PPARα-mediated MOA and therefore are relevant for human health (Hall et al., 2012). Further, according to the available criteria, effects such as cytoplasmic alteration in the presence of liver cell necrosis are considered relevant to humans (Hall et al., 2012).

Additionally, commenters asserted that a 2020 study by Chappell et al. reported evidence demonstrating that the rodent liver effects are not relevant to humans, and that the EPA failed to consider this study. It is important to note that although Chappell et al. (2020) was published after the assessment's literature search cut-off date (USEPA, 2021e, Appendix A; USEPA,

2022d), the EPA considered this paper initially through the Request for Correction process (USEPA, 2022d) and noted that this study specifically assessed evidence for PPARα-driven apoptosis and did not investigate other important potential modes of action or types of cell death, specifically necrosis. The authors state that they could "not eliminate the possibility that necrotic cells were also present." The EPA again considered Chappell et al. (2020), in addition to other studies submitted through public comment (Heintz et al., 2022; Heintz et al., 2023; Thompson et al., 2023), and determined that these studies are unable to explore a necrotic/cytotoxic MOA through transcriptomics with the methods used in these papers since Thompson et al. (2023) states that "there are no gene sets for assessing necrosis in transcriptomic databases." Though the study tests "a gene expression signature indicative of liver cytotoxicity…developed from short-term toxicity studies in rats," it is unclear whether this gene expression signature is indicative of liver cytotoxicity in mice or in studies longer than 4-14 days. This is important because the available HFPO-DA studies demonstrating a constellation of liver lesions are in mice exposed to HFPO-DA for 28 days and longer.

Finally, additional support beyond the data presented in a few transcriptomics-focused studies (Thompson et al., 2023 is a secondary analysis of Chappel et al., 2020 and Heintz et al., 2022 and Heintz et al, 2023 is a review of these three studies) are needed to conclude that PPAR-alpha activation is the sole definitive MOA for HPFO-DA-induced liver effects. For example, evaluation of the relationship between changes in mRNA abundance (gene expression) and functional protein expression for the same protein-coding genes would further the understanding of the downstream effects (i.e., changes in protein) of the predicted PPAR alpha activation and demonstrated PPARalpha binding. In the absence of changes to the PPARalpha gene, as presented in the studies, changes in protein indicators of PPARalpha activation (e.g., Cyp4a in mice, for which some (but not all) mRNA isoforms are differentially expressed in treated mice) could serve as surrogates, to support the predictions from transcriptomics data. It is known that mRNA levels generally explain protein levels in a "steady state" scenario, while it is also true that mRNA does not fully explain protein expression, as there are post-transcriptional and even post-translational events that influence protein expression (Liu et al., 2016). Relatedly, demonstration of alterations in proteins that are involved in the regulation of cell cycle and lipid metabolism that are expected following PPARalpha activation, whether via increased transcription resulting in increased translation or by other mechanisms (e.g., bioactivation or release of protein from cells) (Corton et al., 2014), would support the MOA, but were not measured in the studies. Targeted gene expression analysis of key genes involved in the PPARa signaling pathway to verify the findings from the non-targeted approach (e.g., qPCR) would also increase confidence in the results, albeit not as informative as protein expression.

Relatedly, confirmation of changes to predicted upstream regulators, specifically changes to PPARa at the protein level, has not been presented to accompany the predictions from upstream regulator predictive analysis. To conclusively link PPARa activation to all molecular effects, staining for PPARa in liver sections from animals used in these experiments to confirm that the protein is changed in localization or expression would strengthen the presented predictions. This is particularly important considering the overlap in gene targets of PPARa and other members of

the same nuclear receptor superfamily (e.g., PXR, CAR, and other PPARs (Elcombe et al., 2014)). It also should be noted that the gene set analyses conducted in these studies are based upon gene sets curated using data from publications from a variety of cell types. This is important because different cell types have different baseline transcriptomic landscapes (Zhu et al., 2016), and cell type-agnostic predicted pathways based upon inferences about the transcriptome may or may not be indicative of what is happening in the specific cell type being investigated in practice.

Thompson et al. (2019), Chappel et al. (2020), and Thompson et al. (2023) all demonstrate apoptotic cells which were lesions also identified by the NTP-PWG. Most importantly, the commenter and these cited studies fail to recognize that increased apoptosis is a key criterion to establish a cytotoxic MOA and, as noted above, is inconsistent with a PPARalpha MOA. As outlined in the toxicity assessment (USEPA, 2021e), Felter et al. (2018) "identified criteria for establishing a cytotoxicity MOA, which includes:…2) clear evidence of cytotoxicity by histopathology, such as presence of necrosis and/or increased apoptosis." Overall, following re-review of Chappell et al. (2020) as well as review of the other studies submitted through public comment, the EPA determined that these studies provide evidence for increased apoptosis, which is a key event of a cytotoxic MOA, and therefore they support the mechanistic conclusions of the 2021 HFPO-DA toxicity assessment "that multiple MOAs could be involved in the liver effects observed after GenX chemical exposure" including PPARα and cytotoxicity (USEPA, 2021e).

With respect to claims that the EPA misapplied diagnostic criteria classifying apoptotic and necrotic lesions: as mentioned above, the EPA engaged a pathology working group within the NTP at the National Institutes of Health to perform an independent analysis of the liver tissue slides. Seven pathologists—headed by Dr. Elmore, who was the lead author of the pathology criteria that the commenter cites (Elmore et al., 2016)—concluded that exposure to HFPO-DA caused a "constellation of liver effects" that included cytoplasmic alteration, apoptosis, single cell necrosis, and focal necrosis, and that this full "constellation of lesions" should be considered the adverse liver effect within these studies. The EPA then used the established Hall criteria (Hall et al., 2012) to determine that since liver cell death was observed, all effects, including cytoplasmic alteration, were considered adverse and relevant to humans. The NTP-PWG was comprised of 7 pathologists using the Elmore diagnostic criteria to systematically classify and reach consensus on the observed liver lesions, including Dr. Elmore herself. The analysis included multiple layers of quality control and peer review. The diagnostic evaluation conducted in Thompson et al., 2019 and Chappel et al., 2020 was completed by one pathologist with no quality control as described in the methods sections of those papers. The commenter states that the Thompson et al., 2023 publication "demonstrated that some of the hepatocytes putatively considered necrotic by the NTP-PWG, in fact, stain positive for molecular markers of apoptosis thereby calling into questions the NTP-PWG's diagnoses of necrosis;" however, it is known that apoptosis can lead to secondary necrosis and that this is mediated through Caspase 3 (Rogers et al., 2017), which is the same stain used in Thompson et al., 2023. Additionally, and as described above, the presence of increased apoptotic cells is more consistent with a cytotoxic MOA than with a PPARalpha MOA. For the reasons described above, the EPA is confident that the findings

of the seven-member pathology working group reflect an independent, unbiased, and comprehensive high-quality analysis.

The EPA disagrees with the commenters' assertion about UF application. As noted above, agency guidance (USEPA, 2002a; USEPA, 2022a) has established the appropriateness of the use of UFs to address uncertainty and account for data limitations. UFs reflect the limitations of the data across the five areas used in current EPA human health risk assessment development (referenced above); all individual UFs that are applied are multiplied together to yield the composite or total UF. The EPA guidance states that although a composite UF greater than 3,000 represents "excessive uncertainty" (USEPA, 2002a; USEPA, 2022a), a composite UF can be equal to 3,000. For HFPO-DA, a composite UF of 3,000 was appropriately applied to account for uncertainties, including variability in the human population, database uncertainties, and possible differences in the ways in which humans and rodents respond to HFPO-DA that reaches their tissues. Furthermore, the composite UF of 3,000 and specifically the database UF and subchronic-to-chronic UF used for HFPO-DA was peer-reviewed by a panel of human health risk assessment experts, and the panel supported the application of the database UF of 10 and the subchronic-to-chronic UF of 10 (USEPA, 2021h). Additionally, a UF_A of 3 was appropriately applied, consistent with peer-reviewed EPA methodology (USEPA, 2002a), to account for uncertainty in characterizing the toxicokinetic and toxicodynamic differences between rodents and humans. As noted in the toxicity assessment for HFPO-DA (USEPA, 2021e), in the absence of chemical-specific data to quantify residual uncertainty related to toxicokinetics and toxicodynamic processes, the EPA's guidelines recommend use of a UF_A of 3.

Some commenters claimed that the EPA did not consider available epidemiological evidence showing no increased risk of cancers or liver disease attributable to exposure to HFPO-DA. The EPA disagrees with this comment because the agency considered all available scientific evidence, including epidemiological studies (USEPA, 2021e). The exhibit submitted by the commenter presents an observational analysis comparing cancer and liver disease rates in North Carolina to rates in other states. It does not present the results of a new epidemiological study that included HFPO-DA exposure measures, health outcome measures, or an assessment of association between exposure and health outcome. The exhibit submitted by the commenter consists of a secondary analysis of disease rate information that was collected from various sources and does not provide new, high-quality scientific information that can be used to assess the impact of exposure to concentrations of HFPO-DA on human health.

One commenter stated that the DWI-BW used in the calculation of the HRL/HBWC for HFPO-DA is inappropriate and that the EPA should have used a DWI-BW for general population adults instead of for lactating women. The EPA disagrees with this comment. To select an appropriate DWI-BW for use in derivation of the HRL/HBWC for HFPO-DA, the EPA considered the HFPO-DA exposure interval used in the oral reproductive/developmental toxicity study in mice that served as the basis for chronic RfD derivation (the critical study). In this study, parental female mice were dosed from pre-mating through lactation, corresponding to three potentially sensitive human adult life stages that may represent critical windows of HFPO-DA exposure:

women of childbearing age, pregnant women, and lactating women (Table 3-63 in USEPA, 2019). Of these three, the highest DWI-BW, for lactating women (0.0469 L/kg/day), is anticipated to be protective of the other two sensitive life stages and was used to calculate the HRL/HBWC for HFPO-DA (USEPA, 2024h).

Individual Public Comments and EPA Responses

General Comments

Brian Hackman (Doc. #1539, SBC-042893)

By establishing the MCL's (maximum contaminant levels) and HI (hazard index) values using ASTDR (Agency for Toxic Substances and Disease Registry) data, USEPA has taken data that ASTDR has publicly recognized has not been equated to level of risk, i.e., concentrations above their values do not have a number of people vs. concentration correlation for risk of each and total health effects. By taking the MRL (minimum recommended level) data and reducing the ppt values by additional safety factors, the USEPA has presented an overly conservative maximum contaminant value, where the expectation appears to be that 0 people will be impacted if the MCL is met. However, USEPA has shown this approach is foolish because the Agency set a parts per quadrillion (ppq) standard as a health advisory, showing that the Agency has only emotions and no scientific basis other than simple math and models with numerous pages of assumptions considering absolute worst case values to base its decision making on. This dichotomy of the Agency's de minimus risk approach to protect public health while saying any concentration is a risk is pure insanity to determine, pay for, and enforce, even at the proposed MCL's and HI's in a rush to think that something needs to be done because something can be 'detected'.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document. HAs are beyond the scope of this rulemaking action. They are non-regulatory HAs issued pursuant to a separate authority under SDWA that reflected the best available information at that time. The commenter acknowledges that the EPA uses peer-reviewed models and math to inform its decision-making. These models and math comprise best available science, which, among other science and information, inform the MCLGs and overall NPDWR.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-045877)

Troublingly, EPA has not completed its own human health assessments for PFHxS and PFNA. Instead, it relies on assessments from the Agency for Toxic Substances and Disease Registry (ATSDR). EPA did not oversee the peer review process of the ATSDR document, which covered the assessment of 12 PFAS. ATSDR conducted a letter peer review, which is inconsistent with EPA's own best practices for the peer review of ISAs or HISAs. For instance, as described by ATSDR, the peer reviewers were not provided with any of the public comments before the review [FN11: ATSDR Peer Review Agenda for the Toxicological Profile for Perfluoroalkyls (PFAS), available at:

https://www.atsdr.cdc.gov/sites/peer_review/tox_profile_perfluoroalkyls.html.]. EPA's Peer Review Handbook recognizes that a letter review is appropriate when a work product is "not controversial" and also recognizes that, for HISAs, a panel review is a preferable approach [FN12: U.S. EPA, Peer Review Handbook, 4th edition, 2015, at pages 55-57, available at: https://www.epa.gov/sites/default/files/2015-10/documents/epa_peer_review_handbook_4th_edition_october_2015.pdf.]. The ATSDR health assessments are not a valid substitute for the rigorous SAB peer review that is required for a HISA. Equally important, in describing how to use the ATSDR minimal risk levels that EPA relies upon, ATSDR describes these values as "[i]ntended to serve as screening levels, are used by ATSDR health assessors and other responders to identify contaminants and potential health effects that may be of concern at hazardous waste sites. It is important to note that [Minimal Risk Levels] (MRLs) are not intended to define cleanup or action levels for ATSDR or other Agencies" (emphasis added by ATSDR) [FN13: See ATSDR description of minimal risk levels at: https://www.atsdr.cdc.gov/mrls/index.html.].

EPA Response: In regard to how the EPA considers the ATSDR assessments, please see section 4.3.3 of the EPA response in this *Response to Comments* document. Additionally, commenter mischaracterizes what constitutes Influential Scientific Information (ISI) or Highly Influential Scientific Assessment (HISA) and how the EPA manages peer review for ISI or HISA. The PFNA and PFHxS assessments are not HISA. A scientific assessment is considered HISA when the agency or the OMB Office of Information and Regulatory Affairs (OIRA) Administrator determines that the dissemination could have a potential impact of more than $500 million in any one year on either the public or private sector or that the dissemination is novel, controversial, or precedent-setting, or has significant interagency interest. Neither the EPA Administrator, the CDC director, nor the Administrator of OIRA have determined that the PFNA or PFHxS assessments are HISA. Therefore, the commenter is mistaken that these assessments are HISA. The PFHxS and PFNA toxicity assessments have been peer-reviewed. Letter peer review is consistent with the peer-review process for ISI.

Environmental Protection Network (EPN) (Doc. #1773, SBC-043855)

EPN supports the proposed use of ATSDR's intermediate-duration oral Minimal Risk Levels for PFHxS and PFNA and EPA's reference doses for HFPO-DA and PFBS as representing the best available science on the toxicity of these chemicals.

EPA Response: The commenter agrees with the EPA's approach.

Cleveland Water, City of Cleveland, Ohio (Doc. #1672, SBC-044910)

Section 3.2: PFAS mixture of PFBS, PFNA, GenX, PFHxS

EPA is proposing a HI of 1.0, equal to the MCLG, for the mixture of PFBS, PFNA, GenX, and PFHxS. Each PFAS in this mixture has a proposed HBWC; 10 ppt for GenX, 2000 ppt for PFBS,

10 ppt for PFNA, and 9 ppt for PFHxS. EPA proposed this action to account for dose-additive health impacts of these chemicals in co-occurrence.

As mentioned earlier, EPA has limited occurrence data for these additional PFAS, and is in the process of developing a human health toxicity assessment for PFNA and PFHxS. The human health toxicity assessment should be done before a Regulatory Determination, and certainly before a proposed regulation, as this is paramount to assessing the impact on public health. In contrast, a toxicity assessment from 2021 was used in 2022 to develop a drinking water health advisory for PFBS that is currently the basis for its HBWC. EPA should be using the same method to get to the HBWC if it plans to group these PFAS into a HI.

EPA Response: The EPA disagrees that the agency has limited occurrence data for PFBS, PFNA, HFPO-DA (GenX chemicals), and PFBS. For further discussion on this topic, please see sections 3 and 6 of the EPA response in this *Response to Comments* document. Additionally, the EPA notes that the EPA is using completed human health toxicity assessments for PFHxS, PFNA, HFPO-DA, and PFBS. Two of those assessments were completed by the EPA and two of them were completed by ATSDR. As noted in section 4.3.3 of the EPA response above, the EPA is not required under SDWA to exclusively use EPA assessments to support an NPDWR, and in fact, SDWA's clear direction in Section 1412(b)(3)(A)(i) is to use the best available, peer-reviewed science when developing NPDWRs.

Also, HAs are not a pre-requisite for an NPDWR under the SDWA and there is nothing in the statute or the EPA's historical regulatory practice that suggests that the agency should delay regulation of a contaminant in order to develop a HA first.

American Chemistry Council (ACC) (Doc. #1841, SBC-044834)

EPA has Not Completed an Ongoing Independent Health Hazard Assessment for PFHxS and PFNA and Use of ATDRS MRLs is Not Appropriate

EPA has not completed a toxicity assessment for either perfluorohexane sulfonate (PFHxS) or for perfluorononanoic acid (PFNA) and instead depends on an evaluation of the two substances conducted by the Agency for Toxic Substances and Disease Registry (ATSDR). [FN102: ATSDR. Toxicological Profile for Perfluoroalkyls (2021). (ATSDR PFAS Tox Profile).] However, as recently as February 2023, EPA has indicated that it will conduct assessments of these two chemicals under the Integrated Risk Information System (IRIS) over the next year or so. [FN103: IRIS Program Outlook, February 2023.] ATSDR explicitly states that their toxicity values (minimal risk levels (MRLs)) are "intended to serve as screening levels" (ATSDR 2021 p. 15) and "are not meant to support regulatory action" (ATSDR 2021 p. C-1). The peer review of the single ATSDR assessment, which covered the evaluation of 12 PFAS in one document, was conducted by letter review and was not consistent with EPA's own best practices for a peer review of influential scientific documents that are the basis for a regulation. [FN104: USEPA. Peer Review Handbook, 4th edition. EPA/100/B-15/001. Science and Technology Policy Council

(2025, at 55.] The ATSDR health assessment are not a valid substitute for the rigorous SAB peer review that is required for an influential scientific assessments.

Therefore, it is inconsistent with the intended use of ATSDR MRLs to use them in regulatory rulemaking under the Safe Drinking Water Act. Further, given EPA's stated intention to complete toxicity assessments for these substances in the next year or so, it is inappropriate for EPA to propose and seek comment on MCLs and MCLGs for these substances now, especially because it is not clear what process EPA would use to update the PFNA and PFHxS HBWC values in this proposal when EPA completes its assessment, particularly in light of the planned forthcoming IRIS assessments, for which systematic review protocols were issued for public comment in 2019 and assessments are well underway. [FN105: EPA's IRIS Handbook includes several references to the results of the systematic review for PFHxS and PFNA.] PFHxS and PFNA systematic review outcomes as examples, suggesting that an IRIS assessment for each of the chemicals was well underway.

Laboratory studies with PFHxS and PFNA suggest that the liver is a sensitive target, providing evidence of increased liver weight and centrilobular hepatocellular hypertrophy. Consistent with the criteria provided by Hall et al., however, ATSDR concludes that these effects are not appropriate endpoints for deriving minimum risk levels (MRLs) in the absence of other evidence of liver effects. ATSDR instead relies on reports of other effects in laboratory animal studies, despite evidence that these effects also may be of limited relevance to humans.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document. The EPA notes that the draft EPA IRIS assessment RfD for PFHxS is significantly lower than the ATSDR minimal risk level. While the EPA is not relying on that draft assessment as it has not yet completed peer review, that assessment further demonstrates that PFHxS poses human health risk at low levels and further validates the EPA's determination that PFHxS may affect human health.

PFAS Regulatory Coalition (Doc. #1761, SBC-053399)

Also, EPA's reliance on studies from mice/rats is problematic. The non-cancer toxicological endpoints selected for PFNA, HFPO-DA, PFHxS, and PFBS, and used to support the MCL/MCLGs, are based on laboratory animal responses, which do not correlate with the potential for clinical effects in human populations. Effects seen in mice, such as delayed development and decreased hormone regulation, have highly uncertain relevance in terms of human health. Barring consistency between animals and humans (allowing the basis of the MCL to have positive concordance, which would comply with EPA guidance and policy), toxicological endpoints used in developing MCLs/MCLGs should preferentially rely on human studies and account for adverse PFAS effects leading to clinically-relevant impacts, or have a robust, peer-reviewed and SAB-endorsed rationale for relying solely on rodent results. [FN1: In this context, it should be noted that recent evaluations have raised concerns about the human and animal data that EPA is relying on in this rulemaking, including as to immunotoxicity effects of PFOA and

PFOS. See, e.g., Garvey, et. Al., "Weight of evidence evaluation for chemical-induced immunotoxicity for PFOA and PFOS: findings from an independent panel of experts," Critical Reviews in Toxicology, 53:1, 34-51, DOI: 10.1080.10408444.2023.2194913.]

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document. Additionally, please see sections 4.1.1 and 4.2.2 of the EPA response in this *Response to Comments* document regarding the EPA's use of human studies to support the assessments for PFOA and PFOS. For discussion regarding the EPA's conclusions on immunotoxicity associated with PFOA and PFOS, please see section 4.2.1.4 of the EPA response in this *Response to Comments* document.

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-045883)

3. The HBWCs are overly conservative and are not fit for purpose

EPA uses the following HBWCs for the four PFAS chemicals: 9.0 ppt for PFHxS, 10.0 ppt for HFPO-DA, 10.0 ppt for PFNA [FN20: We note that 88 Fed. Reg. at 18647, EPA refers to the PFNA HBWC as being 100 ppt.], and 2000 ppt for PFBS. For EPA's proposed hazard index approach (used to calculate the MCL for the mixture of these four PFAS), EPA is proposing to calculate the hazard index as the sum total of component PFAS hazard quotients (HQs), calculated by dividing the measured component PFAS concentration in water by these relevant HBWCs. The HBWCs are therefore critical to EPA's proposal to regulate these four PFAS. EPA derives HBWCs using three inputs: oral toxicity values (either the Reference Dose (RfD) or MRL), the body-weight adjusted drinking water intake level for the population of concern (DWI-BW), and the relative source contribution (RSC). However, as noted above, the science supporting the toxicity values for the four contaminants is highly uncertain, is not fit for purpose, and has not undergone the requisite SAB review. Thus, this input in the HBWC is flawed for all four contaminants.

In addition to using highly uncertain toxicity values, EPA uses a default RSC value (i.e., the amount of assumed exposure coming from drinking water) in each HBWC equation. EPA recognizes that "available data on PFHxS exposure routes and sources did not permit quantitative characterization of PFHxS exposure."[FN21: 88 Fed. Reg. at 18646.] Given that lack of data, EPA chose the most conservative default value for the RSC (20%). Combining this RSC with the highly uncertain toxicity values leads to HBWC values that are so low, they are untethered from any realistic measure of potential risk to human health.

In applying the 20% RSC, EPA refers to the EPA 2000 Exposure Decision Tree [FN22: U.S. EPA Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health, EPA- 822-B-00-004, available at: https://www.epa.gov/sites/default/files/2018-10/documents/methodology-wqc-protection-hh-2000.pdf.]. However, this decision tree allows flexibility and encourages the review of information, when available, to make a reasonable determination of exposure, with the goal that the default would not have to be used. For PFHxS, HFPO-DA, PFNA, and PFBS, EPA has not made a sufficient effort to review the existing

information to inform its use of the 2000 Decision Tree. For instance, HFPO-DA is used as a processing aid, and it is not found in consumer products. In determining that a 20% RSC is appropriate, EPA cites to the EPA 2021 HFPO-DA Human Health Toxicity Value Assessment [FN23: U.S. EPA Human Health Toxicity Values for Hexafluoropropylene Oxide (HFPO) Dimer Acid and Its Ammonium Salt (CASRN 13252-13-6 and CASRN 62037-80-3). Also Known as "GenX Chemicals." 2021; available at: https://www.epa.gov/chemical-research/human-health-toxicity-assessments-genx-chemicals.]. However, this assessment does not provide a robust discussion of potential human exposures, and it provides no justification for why a processing aid (chemical intermediate) that is not found in consumer products would warrant a default RSC of 20%. If EPA were to do a simple cursory review and follow its own 2000 Decision Tree, it would lead to the use of a RSC of 80% [FN24: See step 7 of the Exposure Decision Tree as described in U.S. EPA Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health. EPA-822-B-00-004; available at: https://www.epa.gov/sites/default/files/2018-10/documents/methodology-wqc-protection-hh-2000.pdf, at page 4-8; and see also letter from Sheryl Telford, the Chemours Company, addressed to Elizabeth Behl, EPA, submitted to the Proposed Rule docket number EPA-HQ-OW-2022-0114, May 31, 2023 entitled Supplemental Data To Assist in the Development of Health Advisory.]. EPA has provided no information to support the choice of a 20% default for HFPO-DA.

EPA also chose a 20% RSC for PFHxS, PFNA, and PFBS without conducting a robust exposure review. For PFNA and PFHxS, EPA summarizes the occurrence data but still opts for a default of 20% [FN25: U. S. EPA. Maximum Contaminant Level Goal (MCLG) Summary Document for a Mixture of Four Per- and Polyfluoroalkyl Substances (PFAS): GenX Chemicals, PFBS, PFNA and PFHxS, 2023, EPA–822–P–23–004, available at: https://www.epa.gov/system/files/documents/2023-03/PFAS%20HI%20MCLG%20Public%20Review%20Draft%2009%20March%202023.pdf.]. By contrast, New Hampshire, Michigan, Minnesota, and Washington State all chose to use a RSC of 50% for PFHxS [FN26: See ECOS Paper: Processes and Considerations for Setting State PFAS Standards, 2023 Update, available at: https://www.ecos.org/documents/ecos-paper-processes-and-considerations-for-setting-state-pfas-standards-2023-update/.]. Similarly, for PFNA, New Hampshire, New Jersey, Michigan, and Washington state all chose to use a RSC of 50%.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document. For a full discussion of data considered to derive the RSCs for the four PFAS included in the Hazard Index, please refer to USEPA (2024h).

Additionally, as noted by the SAB (USEPA, 2022b), RSC determination depends in part on the RfD value being used. Therefore, it is not necessarily informative to compare RSC derivations when the corresponding toxicity reference values are different (e.g., some of the states noted by the commenter used toxicity reference values for PFNA and/or PFHxS that were different from those used by the EPA). In its report, the SAB stated the following with respect to PFOA and

PFOS: "…because the RSC is based on the portion of the RfD that comes from non-drinking water sources, the choice of the RSC depends on the numerical value of the RfD. The RSC will decrease as the RfD decreases since the non-drinking water exposures represent a higher proportion of a lower RfD. Because the RfDs used in the 2016 EPA HAs and in state drinking water guidelines are several orders of magnitude higher than the RfDs presented in the draft MCLG documents, the RSCs used in the 2016 HESD and by states (discussed on p. 347-348 of the PFOA document) are not relevant to the selection of the RSC in the current draft MCLG documents."

Furthermore, the EPA followed its established process for RSC derivation, which is outlined in the EPA's *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (USEPA, 2000c). See information on RSC derivations for these four PFAS in USEPA (2024h). As noted in the EPA's exposure decision tree approach (USEPA, 2000c), exposure information relevant to the population of concern is a key element of RSC derivation. Following its methodology, the agency determined that for each of these four PFAS, data are insufficient to allow for quantitative characterization of the different exposure sources. Some of the states cited by the commenter (i.e., New Hampshire, Minnesota, New Jersey) appear to have selected a target population for one or more of the PFAS (e.g., breastfed/formula-fed infants) and calculated the RSCs by the subtraction method using predicted blood serum PFAS concentrations. The EPA, however, used the percentage method. As noted in USEPA (2000c), "The subtraction method is considered acceptable when only one criterion is relevant for a particular chemical. The percentage method is recommended in the context of the above goals when multiple media criteria are at issue. The percentage method does not simply depend on the amount of a contaminant in the prospective criterion source only. It is intended to reflect health considerations, the relative portions of other sources, and the likelihood for ever-changing levels in each of those multiple sources (due to ever-changing sources of emissions and discharges)."

<u>The Chemours Company FC, LLC (Doc. #1845, SBC-046065)</u>

4 The use of reference value (RfV) inputs with large disparities in composite uncertainty factors is likely to result in highly uncertain HI MCLG values and difficulties in the interpretation of risk indicated by these values.

In discussing the challenges of the general HI approach, EPA (2023b) notes that the HI can become "highly uncertain" in exposure scenarios where the constituent with the highest HQ has uncertainty in its exposure estimate or where the "RfV was derived using a large composite UF". As discussed above, EPA applied a maximum 3000-fold composite UF in its derivation of the RfD for HFPO-DA. This composite UF is an order of magnitude greater than the composite UF EPA applied to PFBS and PFNA (EPA 2023a). As discussed in Attachment A (Exhibit 3, Section 1), ~90% of IRIS RfD values have composite UF values below 3000. Because EPA considers the RfD for HFPO-DA (and PFHxS) to be so uncertain, the combining of PFAS with different levels of uncertainty can, according to EPA, result in difficulties in the interpretation of such highly uncertain HI MCLG values. As such, the combining of HFPO-DA, PFBS, PFNA, and PFHxS in

the general HI MCLG approach appears incongruent with the PFAS Framework (EPA 2023b). As previously noted, the SAB has not evaluated EPA's proposed implementation of the PFAS Framework to these four PFAS.

EPA Response: For the EPA response to comments on uncertainty, please see section 4.3.3 of the EPA response in this *Response to Comments* document. For the EPA response to comments on SAB review, please see sections 4.3.1 and 4.3.2 of this *Response to Comments* document.

The Chemours Company FC, LLC (Doc. #1845, SBC-046061)

4) The use of reference value (RfV) inputs with large disparities in composite uncertainty factors is likely to result in highly uncertain HI MCLG values and difficulties in the interpretation of risk indicated by these values.

Each of these issues are discussed in detail in the sections that follow.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

The Chemours Company FC, LLC (Doc. #1845, SBC-053391)

3.2 The RfD and MRL values for PFBS, PFNA, and PFHxS potentially lack human relevance.

The RfD or MRL values for PFBS, PFNA, and PFHxS are respectively based on decreased serum total thyroxin, developmental effects (decreased bodyweight and delayed eye opening, preputial separation, and vaginal opening), and thyroid follicular cell hypertrophy/hyperplasia. Considering that some PFAS exhibit overlapping activity, PPARa activation might ultimately be involved in some or all of these endpoints and therefore the human relevance of the RfDs for PFBS, PFNA, and PFHxS may also be uncertain. For example, the PFHxS MRL (developed by ATSDR) is based on thyroid follicular cell hypertrophy/hyperplasia observed in male rats in a subchronic study by Butenhoff et al. (2009). There are well-documented MOAs for thyroid effects in rodents, some of which are widely believed to lack human relevance. One such MOA involves activation of nuclear receptors in the liver (viz., CAR and PXR) resulting in induction of liver enzymes that decrease circulating thyroid hormone levels thereby causing an increase in thyroid stimulating hormone (TSH) that promotes thyroid follicular cell hyperplasia that can, under prolonged circumstances, lead to thyroid tumors in rodents. Notably, ATSDR (2021) states, "There is some uncertainty regarding the selection of thyroid alterations as the critical effect. Butenhoff et al. (2009a) suggested that the histological alterations in the thyroid may be secondary to the liver effects (hepatocellular hypertrophy)." Prior to this statement, ATSDR also states, "Increased liver weight and centrilobular hepatocellular hypertrophy were also observed in the males at ≥3 mg/kg/day. Consistent with the Hall et al. (2012), the liver effects were not considered a relevant endpoint for humans. Although there is uncertainty regarding the exact, and possibly multiple, mechanism(s) for these liver effects, peroxisome proliferation is a likely

contributor, a mechanism that cannot be reliably extrapolated to humans (Hall et al. 2012)." Taken together, ATSDR was uncertain of the human relevance of the thyroid effects induced by PFHxS and clearly viewed a potential preceding effect (viz., hepatocellular hypertrophy) as "not relevant to humans". Notably, the liver effects not considered relevant to humans by ATSDR are similar to those serving as the basis of EPA's RfD for HFPO-DA. EPA adjusted the ATSDR MRL value down to 2E-6 mg/kg-day; similar to the RfD for HFPO-DA, the RfD for PFHxS is orders of magnitude lower than the Cramer Class III TTC (i.e., indicating potential problems with the toxicity value). Finally, EPA's RfD for PFBS is based on thyroid hormone effects (viz., decreased total thyroxine in newborn mice after gestational exposure via the mother) that might also be secondary to changes in the liver enzymes.

EPA Response: The EPA disagrees. Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Pennsylvania Department of Environmental Protection (Doc. #1626, SBC-052944)

• The HBWCs appear to be calculated in the same way as MCLGs. Since they are calculated the same way, it is not clear why EPA introduced the new term HBWC instead of continuing to use the term MCLG. DEP requests clarification on what if any distinction exists between the terms MCLG and HBWC.

EPA Response: In this instance, the EPA identified the HRL to evaluate occurrence data and the likelihood of potential risk to human health for the PFAS for which the EPA is making an individual final regulatory determination and/or a final regulatory determination as part of a PFAS mixture. The EPA identified the HRL as the level below which adverse health effects over a lifetime of exposure are not expected to occur, including for sensitive populations and life stages, allowing an adequate margin of safety. Following this analysis, the agency determined that PFHxS, PFNA, and HFPO-DA meet the SDWA criteria to make individual regulatory determinations. The EPA also determined that combinations of these three PFAS and PFBS meet the SDWA criteria to make a regulatory determination for their mixtures.

The agency developed individual HBWCs for PFHxS, PFNA, HFPO-DA, and PFBS for inclusion in the Hazard Index equation to derive the final Hazard Index MCLG to protect against dose additive effects associated with exposure to mixtures of two or more of these four PFAS. The HBWC is akin to an MCLG in that it reflects a level below which there are no known or anticipated adverse effects over a lifetime of exposure, including for sensitive populations and life stages, and allows for an adequate margin of safety. The HBWCs are not MCLGs for purposes of the Hazard Index PFAS MCLG because the HBWCs are inputs in the equation to derive the MCLG for PFAS mixtures, but the HBWCs and MCLGs represent the same level of protection to meet the statutory definition of MCLG. For PFHxS, PFNA, and HFPO-DA, each of the three HBWCs are equivalent to their final individual MCLGs. The EPA edited the description of HRL and HBWC to clarify that they also meet the definition of MCLG.

The EPA is finalizing individual MCLGs for PFHxS, PFNA, and HFPO-DA as follows: PFHxS MCLG = 10 ng/L; HFPO-DA MCLG = 10 ng/L; and PFNA MCLG = 10 ng/L. The technical basis for why each of these levels satisfies the statutory definition for MCLG is described in section III of the preamble (and is the same technical basis the EPA used to explain the levels identified as the HBWCs). These MCLGs are expressed with one significant digit and are based on an analysis of each chemical's toxicity (i.e., reference dose/minimal risk level), appropriate exposure factors (i.e., DWI-BW), and consideration of exposure sources beyond drinking water (RSC) (USEPA, 2024h). The EPA is deferring its individual regulatory determination for PFBS and not finalizing an individual MCLG for PFBS at this time. However, since the EPA has determined that PFBS meets the SDWA criteria when considered in a PFAS mixture with PFHxS, PFNA, and/or HFPO-DA, PFBS is included (with an HBWC of 2,000 ng/L (ppt)) as an input value in the final PFAS mixture Hazard Index MCLG (USEPA, 2024h).

Massachusetts Department of Environmental Protection (MassDEP) (Doc. #1726, SBC-045177)

Use of body weight-adjusted drinking water intakes (DWI-BWs)

EPA selected DWI-BWs for each PFAS included in the HI approach based on evaluation of the critical study used to derive the chronic reference dose. This led to selection of the DWI-BW for lactating women for HFPO-DA and PFNA, the DWI-BW for women of childbearing age for PFBS, and the DWI-BW for adults within the general population for PFHxS. MassDEP disagrees with this application of variable DWI-BWs. MassDEP recommends that EPA select the drinking water intake for the most sensitive population or life stage identified from evaluation of the database as a whole, rather than solely based on the critical study for a particular PFAS.

Two lines of evidence support the use of the DWI-BW for the most sensitive population or life stage for HFPO-DA, PFNA, PFBS, and PFHxS. First, EPA's 2023 Draft Toxicity Assessment and Proposed Maximum Contaminant Level Goal in Drinking Water documents for PFOA [FN2: EPA 2023b. Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctanoic Acid (PFOA) in Drinking Water, Public Comment Draft. U.S. Environmental Protection Agency, Office of Water (4304T), Health and Ecological Criteria Division, Washington, DC 20460. EPA-822-P-23-005.] and PFOS [FN3: EPA 2023c. Toxicity Assessment and Proposed Maximum Contaminant Level Goal for Perfluorooctane Sulfonic Acid (PFOS) in Drinking Water, Public Comment Draft. U.S. Environmental Protection Agency, Office of Water (4304T), Health and Ecological Criteria Division, Washington, DC 20460. EPA-822-P-23-007], the PFAS with the largest databases, provide evidence for the similarity of noncancer health effects and effect levels across the life stages, health outcomes and endpoints. The candidate Reference Doses (RfDs) for PFOA and PFOS were developed from different health outcomes and endpoints evaluated at different life stages, yet the health outcome specific RfDs EPA developed for PFOA and PFOS were both within a factor of 2 across the four health outcomes with sufficient evidence for evaluation. PFAS with smaller databases may not have data to evaluate a full array of health outcomes, limiting the certainty that the critical effects to the most sensitive life stage have been sufficiently evaluated. Given the growing body of evidence

supporting a wide range of health outcomes across life stages, it is prudent to assume that, until demonstrated otherwise, PFAS may have effects at sensitive life stages.

Second, as described in the Mixture document, evidence supports dose-additive effects from co-exposure to PFAS. However, the relative contribution of any particular PFAS to produce additive response to any of the multiple health outcomes associated with different life stage sensitivities is not known.

While the difference in drinking water concentrations (MCLGs) derived using the lowest and highest DWI-BW is small, i.e., well within the margin of uncertainty assumed for the RfD, adopting the ingestion rate for the most sensitive population best represents the available evidence on the health effects of PFAS.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Earthjustice et al. (Doc. #1808, SBC-046115)

IV. EPA Should Strengthen its Proposed Rule to Protect the Public and Promote Compliance

A. EPA Should Revise its Health Based Water Concentrations ("HBWCs") to Fully Address the HI PFAS' Harms to Susceptible Populations

EPA's proposed MCLG and MCL for the HI PFAS incorporate HBWCs to indicate the levels at which PFBS, GenX, PFNA, and PFHxS pose no known adverse health effects. [FN144: As described above, EPA divides the measured concentration of each HI PFAS by its HBWC to calculate a hazard quotient, which is then added to the other HI PFAS' hazard quotients to calculate the hazard index.] When establishing MCLs, the SDWA requires EPA to consider contaminants' effects not only on the general population but also on "groups . . . such as infants, children, pregnant women, the elderly, individuals with a history of serious illness, or other subpopulations that are identified as likely to be at greater risk of adverse health effects due to exposure to contaminants in drinking water[.]" [FN145: 42 U.S.C. § 300g–1(b)(3)(C)(i)(V) (requiring EPA to assess health impacts on greater-risk populations when establishing MCLs).]However, EPA's proposed HBWCs fail to address risks to infants and other populations that experience the greatest risks from the HI PFAS, leaving those populations exposed to serious harm. In its final rule, we urge EPA to revisit and strengthen its HBWCs for each of the HI PFAS.

Developing infants and children are most at risk of the long-term effects of PFAS exposure. There are two reasons for this. First, the fetal and early childhood life stages are when the body's systems are being established and developed. Small changes that disrupt or permanently alter the course of development can increase the risk of later-life disease. Second, formula fed infants and lactating people consume more drinking water per unit of body weight. [FN146: EPA, EPA/600/R-18/259F, Update for Chapter 3 of the Exposure Factors Handbook: Ingestion of Water and Other Select Liquids, Off. of Rsch. and Dev., at 3-14, 3-23 (Feb. 2019),

https://www.epa.gov/sites/default/files/2019-02/documents/efh_-_chapter_3_update.pdf.] Infants, for example, may be exposed to PFAS via contaminated breastmilk and/or infant formula prepared with PFAS contaminated water. It is important that these factors are adequately accounted for in the MCL or health-based value calculation process, since developing children are both the most sensitive population as well as the population with the highest estimated exposure.

Unless there is substantial data showing that an endpoint studied in adults is not relevant in infants and children, it is EPA's responsibility to set standards that are protective of all populations. Furthermore, the assumption for PFAS should be that there is a need to protect infants and children. Given the similarity among PFAS, EPA does not require developmental studies each particular PFAS to conclude that infants and children are susceptible to harm from exposure. In this case, drinking water intake assumptions for infants and children should be used. As stated by EPA in the Drinking Water Health Advisory for PFBS, "[w]hen multiple potentially sensitive populations or life stages are identified based on the critical effect or other health effects data (from animal or human studies), EPA selects the population or life stage with the greatest [drinking water intake rate adjusted for body weight] DWI-BW" because it is the most health protective." [FN147: EPA, EPA/822/R-22/006, Drinking Water Health Advisory: Perfluorobutane Sulfonic Acid (CASRN 375-73-5) and Related Compound Potassium Perfluorobutane Sulfonate (CASRN 29420-49-3), Off. of Water, at 18–19 (June 2022), https://www.epa.gov/system/files/documents/2022-06/drinking-water-pfbs-2022.pdf.] Despite this strong statement and the potential for developmental effects from PFAS exposure in the Proposed Rule, EPA consistently failed to use the more protective DWI-BW for infants or children, even when the critical effect is developmental, as is the case for PFNA. EPA chose a DWI-BW for lactating women for PFNA and GenX, a DWI-BW for "women of childbearing age" for PFBS and a DWI-BW for the adult general population for PFHxS. [FN148: EPA, EPA-822-P-23-004, Maximum Contaminant Level Goal (MCLG) Summary Document for a Mixture of Four Per- and Polyfluoroalkyl Substances (PFAS): HFPO-DA and its Ammonium Salt (also known as GenX Chemicals), PFBS, PFNA, and PFHxS, Off. of Water, at 9 (Mar. 2023), https://www.regulations.gov/document/EPA-HQ-OW-2022-0114-0906.] The application of DWI-BW for these PFAS is not the most health protective and puts infants and children at risk.

Health protective approaches are used in other steps of risk assessment when evidence is lacking, for example, when deriving a chronic reference dose in the absence of a chronic study. Risk assessors often determine the risk of acute, subchronic, and chronic exposures to a chemical. For PFAS in drinking water, the most protective and realistic exposure scenario is typically a chronic exposure. However, since chronic exposure studies are not always available, EPA derives reference doses ("RfDs") for chronic exposure from subchronic studies by applying an uncertainty factor instead of improperly assuming a RfD based on a subchronic exposure is protective of chronic exposure.

Furthermore, NAS has recommended the use of an additional uncertainty factor of 10 to ensure protection of fetuses, infants and children groups which are often are not sufficiently protected

from toxic chemicals such as pesticides by the traditional intraspecies uncertainty factor. [FN149: Nat'l Acad. of Sci., Pesticides in the Diets of Infants and Children. National Research Council 361 (1993), https://www.ncbi.nlm.nih.gov/books/NBK236275/.] Congress adopted this requirement in the Food Quality Protection Act ("FQPA") for pesticides in or on foods. [FN150: 21 U.S.C. § 346a(b)(2)(C)(ii)(II).] The uneven application of this additional uncertainty factor to protect these vulnerable populations across EPA is concerning. Considering the many health effects linked to PFAS that affect these vulnerable populations and the substantial data gaps on exposure and toxicity of these compounds in complex mixtures, EPA must do a better job of protecting sensitive and vulnerable populations in its assessments and actions on all toxic chemicals, regardless of their regulatory context.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document. With regard to the comment on the NAS recommendation for an additional uncertainty factor, each of the chronic toxicity reference values for the four PFAS included in the Hazard Index already take into account the strength of the database as a whole: the HFPO-DA and PFBS RfDs each include a UF_D of 10, and the PFNA and PFHxS minimal risk levels each include a modifying factor (MF) of 10 for database deficiencies.

Earthjustice et al. (Doc. #1808, SBC-053412)

We reiterate our support for EPA's use of a hazard index, or some other method that accounts for adverse effects associated with mixtures of the HI PFAS, when setting its MCLG and MCL. In order to comply with the SDWA and protect communities who are exposed to those PFAS mixtures, however, the HBWCs that EPA uses to calculate the hazard index must reflect the "best available science" on those chemicals' risks to infants and other susceptible subpopulations. EPA's proposed HBWCs would permit unsafe levels of the HI PFAS to remain in drinking water and diminish the protectiveness of EPA's proposed MCLs. We urge EPA to strengthen the HBWCs in its final rule.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Connecticut Department of Public Health (CT DPH) (Doc. #1745, SBC-052997)

CT DPH also makes the following comments regarding the exposure factors used in EPA's preliminary regulatory determination for PFHxS, HFPO-DA, PFNA, and PFBS:

EPA selected DWI-BWs from three subpopulations- adults within the general population, lactating women, and women of child-bearing age- to derive the HBWCs for PFHxS, PFNA and PFBS, respectively. CT DPH recommends that EPA consider infants as a sensitive life stage for these PFAS and select the DWI-BW of infants to calculate the HBWCs. This is because the most sensitive health effects identified for the three PFAS were thyroid and developmental effects.

Infants are known to be more sensitive to these health effects, as recognized by USEPA's toxicological assessments. For example, although it was the female dams which were exposed to PFBS through ingestion in the critical study (Feng et al. 2017), the identified critical effect (developmental) is on the fetuses. Due to the lack of toxicokinetic information regarding lactational transfer rates, it is unclear whether the HBWC derived using the exposure factor for lactating women would also be protective to bottle-fed infant who consumes formula made with drinking water of the same PFBS concentration. For this reason, CT DPH has developed drinking water action levels for PFNA and PFHxS using infant ingestion rates. USEPA should also apply the infant water ingestion rate when calculating the HBWCs to protect the health of formula-fed infants.

CT DPH agrees that deriving HBWCs using upper percentiles of drinking water ingestion rates is protective for most of the general population. EPA used the exposure factors from the most recent Exposure Factor Handbook (Chapter 3), an appropriate source for this purpose. However, CT DPH recommends using 95th percentile instead of 90th percentile of the ingestion rate in the specified population to be more protective to the general population. This would also be consistent with the Exposure Factor Handbook's recommendations (Tables 3-1 and 3-3).

EPA Response: The EPA disagrees with this comment. The EPA selected the corresponding DWI-BW for the relevant sensitive population or life stage from the Exposure Factors Handbook (USEPA, 2019) based on the best available, peer-reviewed science taking into account the relevant sensitive population(s) or life stage(s). With respect to the comment about using the infant DWI-BW instead of the DWI-BW for women of child-bearing age for PFBS, the EPA notes that the agency followed its guidance for selecting an appropriate DWI-BW (see section 4.3.3 of the EPA response in this *Response to Comments* document). The EPA considered the PFBS exposure interval used in the toxicity study in mice that served as the basis for chronic RfD derivation (the critical study). In this study, thyroid effects (decreased serum total thyroxine) were observed in newborn mice following gestational exposure. To be clear, the critical study exposed mice to PFBS only during pregnancy and not during postnatal development; newborn mice in early postnatal development, which would correspond to the human infancy life stage, were not exposed to PFBS. Since dosing in the study did not continue beyond gestation, a DWI-BW for infants (which would represent exposure beyond gestation) would not appropriately correspond to the exposure window in the critical study and was therefore not selected. The exposure window in the study corresponds to two potentially sensitive human adult life stages: women of childbearing age, and pregnant women (Table 3-63 in USEPA, 2019). Of these two, the higher DWI-BW, for women of childbearing age (0.0354 L/kg/day), is anticipated to be protective of the other sensitive life stage and was used to calculate the HBWC for PFBS.

With respect to use of the 90th percentile DWI-BW, the EPA followed agency guidance (USEPA, 2000b), which recommends selection of the 90th percentile DWI-BW to be "protective of a majority of the population" (USEPA, 2000b). Using the 90th percentile DWI-BW is justified because it is a reasonable, appropriately conservative (health protective), high-end exposure assumption that results in protection of the general population as well as sensitive populations or

life stages (USEPA, 2000b,d), consistent with the statute's directive that the MCLG allows for an adequate margin of safety (1412(b)(4)(A)). The EPA has precedent for using the 90th percentile DWI-BW to develop MCLGs (e.g., USEPA, 2000c), and for routine SDWA statutory processes (e.g., Six Year Review, Regulatory Determination). Other EPA programs also use a default 90th percentile drinking water intake (DWI), for example when conducting human health assessments for Superfund sites (USEPA, 2014c) and developing human health criteria for ambient waters (USEPA, 2000c).

Connecticut Department of Public Health (CT DPH) (Doc. #1745, SBC-045214)

c) The HBWCs, which are the denominators of the HQs that make up the HI, are not just different in terms of the health effect they represent (i.e. the HBWCs are based on different health endpoints). The HBWCs were also derived using different ingestion rates and target receptors (e.g. general adults, lactating women etc.) with different exposure durations. The various exposure assumptions the four HQs based on created a significant challenge when interpreting the meaning of the general HI, which leads to more challenging risk communication and management. For example, the risk message would need to target pregnant women as a sensitive population when the HQ for PFNA exceeds 1.0. This would be different from the risk message for a MCL exceedance solely triggered by GenX.

EPA Response: An HBWC represents the level below which adverse health effects over a lifetime of exposure are not expected to occur, including for sensitive populations and life stages and with an adequate margin of safety (as required by SDWA). Each of the HBWCs that make up the Hazard Index is based on the most sensitive known adverse health outcome (the critical effect) and a DWI-BW that reflects potentially sensitive populations or lifestages, based on available data for each contaminant. This approach ensures that each HBWC protects not only the general population but also sensitive populations and lifestages, resulting in a health-protective Hazard Index approach. Please see section 4.3.3 of the EPA response in this *Response to Comments* document for information about the EPA's approach to DWI-BW selection, and section 1.2 for additional discussion on PFAS risk communications.

Minnesota Pollution Control Agency (MPCA) (Doc. #1569, SBC-052822)

3) EPA requests comment on the derivation of the health-based water concentrations (HBWCs) for each of the four PFAS considered as part of the HI.

MPCA response:

• MPCA agrees with the methods used to derive HBWCs for the four PFAS considered as part of the HI.

EPA Response: The commenter agrees with the EPA's approach.

3M Company (Doc. #1774, SBC-045665)

The lack of peer review and submission to the SAB is significant. As noted above, it expressly violates the SDWA. The lack of peer review has even resulted in EPA making basic errors that would have been identified during the peer review process. For example, EPA makes an arithmetic error in its derivation of the HBWC for PFHxS (USEPA 2023l). Using EPA's inputs in Table 4 of the Hazard Index document (USEPA 2023l), the HBWC would be 12 ppt, and applying one significant figure, the final HWBC should be 10 ppt, not 9 ppt. This error must be corrected. This error also signals an absence of even basic quality assurance. All of EPA's calculations require comprehensive peer review before the NPDWR is finalized, and EPA must submit its proposed MCLG and NPDWR for the HI PFAS, including the HBWCs, to SAB for comment.

EPA Response: The commenter is incorrect. The toxicity assessments for PFHxS, PFNA, HFPO-DA, and PFBS have been peer reviewed. For the EPA response to comments on peer review, please see sections 4.3.1 and 4.3.2 of the EPA response in this *Response to Comments* document. The agency has corrected the PFHxS HBWC value in this NPDWR. The correct HBWC for PFHxS is 10 ng/L (ppt).

Silent Spring Institute (Doc. #1784, SBC-045801)

2. Setting standards for PFHxS, HFPO-DA, PFNA, and PFBS, in addition to PFOA and PFOS, is appropriate given strong evidence for adverse health effects and their prevalence in public water supplies.

We found the determination of the health-based water concentrations (HBWCs) for PFHxS, HFPO-DA, PFNA, and PFBS appropriate and protective of noncancer health effects. Overall, ATSDR concluded that there is strong evidence that links environmental exposures to these PFAS with a range of health effects, including elevated cholesterol, thyroid disease, ulcerative colitis, pregnancy-induced hypertension, obesity, impaired immune response to vaccinations, and cancer.[REF22: ATSDR. Toxicological Profile for Perfluoroalkyls. Atlanta, GA, 2021.] While many studies have focused on PFOS and PFOA, a growing number of studies have demonstrated similar effects from other PFAS compounds, including these.

In its toxicological profile for perfluoroalkyls, ATSDR documented evidence of low-dose PFHxS and PFNA toxicity and their high prevalence in U.S. water systems. ATSDR's derived Minimum Risk Levels are robust and authoritative, so the use of ATSDR's Minimum Risk Levels for PFHxS and PFNA as HBWCs is justified. These HBWCs are likely to be protective of health effects. The HBWCs are generally consistent with assessments by other expert authoritative bodies, such as MCLs developed by state health and environmental agencies. For example, New Hampshire established an MCL for PFHxS of 18 ng/L, and Michigan, Washington, and New Jersey each established MCLs for PFNA in the range of 6-13 ng/L. It should be noted, however, that ATSDR's Minimal Risk Levels for PFHxS (2 ng/kg-day) and PFNA (3 ng/kg-day) exceed EFSA's tolerable daily intake of 0.63 ng/kg-day for a group sum of PFOA, PFOS, PFHxS, and

PFNA. These data highlight the need to set the HBWCs for PFNA and PFHxS to levels as low as feasible to be protective of the most sensitive health effects.

EPA has conducted a thorough risk assessment of PFBS and HFPO-DA in their derivation of these HBWCs. Nevertheless, the appropriate HBWCs for PFBS and HFPO-DA could be lower than what EPA is proposing in order to account for PFAS's toxicokinetic variability across species, which can be accounted for in two ways: (1) using a PBTK approach to estimate an internal dose to account for toxicokinetic variability between rodents and humans, and (2) increasing the interspecies uncertainty factor (UFA) from 3 to 10, or possibly higher based on careful evaluation of all available data. These changes may result in lower HBWCs for PFBS and HFPO-DA.

EPA Response: For the EPA response to comments on the appropriateness of HBWCs and the use of ATSDR minimal risk levels, please see section 4.3.3 of the EPA response in this *Response to Comments* document. Additionally, as noted in the toxicity assessments for PFBS and HFPO-DA (USEPA, 2021d; USEPA, 2021b), the EPA followed its guidance (e.g., USEPA, 2002a; 2011; 2014a) to determine the most appropriate way to account for toxicokinetic variability across species. For both PFBS and HFPO-DA, the EPA determined that data were inadequate to support derivation of data-derived extrapolation factors. Therefore, consistent with EPA guidance, the default approach of the use of $BW^{3/4}$ scaling to obtain a human equivalent dose was used. Also, a UF_A of 3 was appropriately applied, consistent with peer-reviewed EPA methodology (USEPA, 2002a), to account for uncertainty in characterizing the toxicokinetic and toxicodynamic differences between rodents and humans. As noted in the toxicity assessments for PFBS and HFPO-DA (USEPA, 2021d; USEPA, 2021b), although this scaling addresses most aspects of cross-species extrapolation of toxicokinetic processes, there is some residual uncertainty for toxicokinetics and uncertainty around toxicodynamic processes. In the absence of chemical-specific data to quantify this uncertainty, the EPA's guidance recommends use of a UF_A of 3.

Illinois Farm Bureau (IFB) (Doc. #1630, SBC-043137)

The most glaringly overlooked and/or underestimated data includes:

• Significant uncertainty regarding the health risks at the proposed MCL levels for all six PFAS - EPA's Reference Dose–for PFNA, GenX, PFHxS, and PFBS chemicals is based entirely on laboratory animal studies, even though EPA itself advises "Adequate human data are the most relevant for assessing risks to humans." The World Health Organization's recent study on potential guidelines for water quality, for example, proposed 100 ppt based on the most relevant public health data and seems to be consistent with known risk. EPA's Science Advisory Bo'rd expressed these same sentiments and determined that EPA needs more transparency in how they assess studies, better information on the metrics of including specific studies or not, and they must include more human studies in their assessment.

[FN1:https://sab.epa.gov/ords/sab/f?p=114:0:6179756424602:APPLICATION_PROCESS=REPORT_DOC:::REPORT_ID:1105]

EPA Response: Please see the EPA response to comment Doc. #1642, SBC-043484 in section 4.3.3 in this *Response to Comments* document and section 4.3.3 of the EPA response in this *Response to Comments* document. Regarding the World Health Organization (WHO) guidelines, please see section 4.2.6 of the EPA response in this *Response to Comments* document.

American Farm Bureau Federation et al. (Doc. #1642, SBC-043484)

[They have identified the following areas of concern regarding the agency's development of this rule:]

• There is limited understanding of risk at these levels. EPA's Reference Dose for PFNA, GenX, PFHxS, and PFBS chemicals is based entirely on laboratory animal studies, even though EPA itself advises, "Adequate human data are the most relevant for assessing risks to humans." There is significant uncertainty regarding the health risks at the proposed MCL levels for all six PFAS. The World Health Organization's recent study on potential guidelines for water quality, for example, proposed 100 ppt based on the most relevant public health data and seems to be consistent with known risk. EPA's Science Advisory Board expressed these same sentiments and determined that EPA needs more transparency in how they assess studies, better information on the metrics of including specific studies or not, and they must include more human studies in their assessment. [FN3: https://sab.epa.gov/ords/sab/f?p=114:0:6179756424602:APPLICATION_PROCESS=REPORT_DOC:::REPORT_I D:1105]

EPA Response: The EPA disagrees. SDWA requires that to the degree that the EPA's action is based on science, the EPA must use "the best available, peer reviewed science." The HBWCs are based on the best available science—peer-reviewed, publicly available assessments for HFPO-DA (USEPA, 2021e), PFBS (USEPA, 2021d), PFNA (ATSDR, 2021), and PFHxS (ATSDR, 2021) provide the oral toxicity reference values (i.e., RfD or minimal risk level) used to calculate the HBWCs; the DWI-BW selected for each of the four PFAS takes into account the relevant sensitive population(s) or life stage(s); and RSCs are determined based on a literature review of potential exposure sources of the four PFAS (USEPA, 2000c). Additionally, as noted in the EPA's *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a) and *A Review of the Reference Dose and Reference Concentration Process* (USEPA, 2002a), animal studies can provide the basis for toxicity reference values when adequate human studies are not available.

The EPA notes that the commenter took the SAB PFAS Review panel's comments out of context; the SAB's comments regarding transparency, study inclusion/exclusion, and epidemiological studies were specific to the draft documents and available data for PFOA and PFOS (USEPA, 2021b; USEPA, 2021k). These comments should not necessarily be applied to the HBWCs or MCLGs for HFPO-DA, PFBS, PFNA, or PFHxS.

Please see section 4.1.3 of the EPA response in this *Response to Comments* document regarding how the EPA accepted the SAB's recommendations for the PFOA and PFOS toxicity assessments. Additionally, see the EPA response to SAB Comment document (USEPA, 2023d). Regarding the conclusions of the WHO assessment, please see section 4.2.6 of the EPA response in this *Response to Comments* document.

California Farm Bureau Federation (Doc. #1704, SBC-045068)

[For example, the U.S. Chamber analysis highlights the following:]

• There is limited understanding of risk at these levels. EPA's Reference Dose for PFNA, GenX, PFHxS, and PFBS chemicals is based entirely on laboratory animal studies, even though EPA itself advises "Adequate human data are the most relevant for assessing risks to humans." There is significant uncertainty regarding the health risks at the proposed MCL levels for all six PFAS. The World Health Organization's recent study on potential guidelines for water quality, for example, proposed 100 ppt based on the most relevant public health data and seems to be consistent with known risk. EPA's Science Advisory Board expressed these same sentiments and determined that EPA needs more transparency in how they assess studies, better information on the metrics of including specific studies or not, and inclusion of more human studies in their assessment [FN2: See Science Advisory Board Letter to Administrator Regan, August 22, 2022, available at: https://sab.epa.gov/ords/sab/f?p=114:0:6179756424602:APPLICATION_PROCESS=REPORT_DOC:::REPORT_ID:1105].

EPA Response: Please see the EPA response to comment Doc. #1642, SBC-043484 in section 4.3.3 in this *Response to Comments* document.

3M Company (Doc. #1774, SBC-045671)

ii. EPA's relative source contribution value for PFHxS, HFPO-DA, PFNS, and PFBS is not based on the best available science

The relative source contribution (RSC) term used to assign exposure contribution from drinking water is a key element of MCL derivation. The smaller the RSC, the more protective the drinking water regulatory limit is in order to account for other potential sources of exposure. EPA chose the 20 percent default RSC value for HFPO-DA, PFHxS, PFNA and PFBS to develop the HBWCs used in the HI-MCLG, citing insufficient data to calculate a substance-specific RSC. EPA guidance provides that the 20 percent default should only be used when data to characterize other exposure sources is insufficient.

In its comments on the PFOA and PFOS MCLG derivation, the SAB suggested the EPA more clearly justify the 20 percent default value, yet in the documentation for PFOA, PFOS and PFAS mixture, EPA continues to stress that data are not sufficient to characterize exposures for individual substances (USEPA 2023j). While EPA states there are not sufficient data to calculate

substance-specific RSC values for the various substances, the agency nonetheless presents several pages of scientific literature regarding substance occurrence in various media (e.g., dietary sources, indoor dust, soil, sediment) (USEPA 2023e, 2022a,b). The HFPO-DA RSC development documentation cites 52 studies, 14 "gray literature sources" and 3 additional references. For PFBS, 183 peer-reviewed and grey literature references were identified that characterized occurrence in drinking water, groundwater, surface water, dietary sources, consumer products, indoor dust, indoor air, ambient air, and soil (USEPA 2022b). For PFNA and PFHxS, 176 and 177 peer-reviewed studies, respectively, and at least 12 grey literature sources included occurrence data for ambient air, indoor air, consumer products, dust, food, groundwater, drinking water, surface water, sediment, soil, and human blood/serum/urine (USEPA 2023e). There is no clear explanation for why the numerous studies presented do not provide sufficient data to calculate substance-specific RSCs, as recommended by EPA's own guidance.

In addition to the studies presented by EPA for each of the four PFAS, other studies have directly characterized exposure sources for various PFAS. Ericson et al. (2008) determined that drinking water exposure to PFCs (including PFNA and PFHxS) may be as important as the dietary pathway. Vestergren et al. (2012) found that drinking water intake contributed 36–53 percent of the total exposure for PFHxS, PFHpA, and PFHxA.

Given the number of studies and breadth of exposure sources evaluated, inferences can reasonably be made about exposure from various sources using occurrence and concentration data presented. When the currently available data cited by EPA and the studies that directly show water is a primary contributor to exposure for each of the four HI-PFAS are considered collectively, there is likely sufficient support for chemical-specific RSC terms, similar to the chemical-specific values developed for PFOA by several states (Lindborg et al. 2022). EPA suggests that there were insufficient US-based studies, but 47, 50, and 59 of the studies presented for PFNA, PFHxS, and PFBS, respectively, were US-based (USEPA 2023e, 2022b). There is also no evidence that EPA evaluated the RSC based on these studies. Rather, EPA presented a summarized table of the concentration ranges, with no indication or evaluation of how the study findings relate to exposure contribution. This directly contradicts the intended application of EPA's Exposure Decision Tree methodology (USEPA 2000b).

EPA Response: please see section 4.3.3 of the EPA response in this *Response to Comments* document. Furthermore, the EPA followed its established process for RSC derivation, which is outlined in the EPA's *Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health* (USEPA, 2000c). See information on RSC derivations in USEPA (2024h). As noted in the EPA's exposure decision tree approach (USEPA, 2000c), exposure information relevant to the population of concern is a key element of RSC derivation. Following its methodology, the agency determined that for each of these four PFAS, data are insufficient to allow for quantitative characterization of the different exposure sources.

<u>New Hampshire Department of Environmental Services (NHDES) (Doc. #1690, SBC-044343)</u>

Additionally, in the absence of a full review by EPA IRIS we suggest EPA include review of the RfDs for PFHxS and PFNA developed by other states. This includes those recommended by NHDES (NHDES, 2019; Ali et al., 2019), Minnesota Department of Health (MDH, 2020) and New Jersey Department of Environmental Protection (NJ DWQI, 2015).

• NHDES. (2019) Technical Background Report for the June 2019 Proposed Maximum Contaminant Levels (MCLs) and Ambient Groundwater Quality Standards (AGQSs) for Perfluorooctane sulfonic Acid (PFOS), Perfluorooctanoic Acid (PFOA), Perfluorononanoic Acid (PFNA), and Perfluorohexane sulfonic Acid (PFHxS). NHDES, Environmental Health Program. Link [Link: https://www.des.nh.gov/sites/g/files/ehbemt341/files/documents/r-wd-19-29-final.pdf] .

Regulatory Toxicology and Pharmacology: RTP, 108, 104452. Link [https://www.sciencedirect.com/science/article/pii/S0273230019302168?via%3Dihub]

• MDH. (2020) Toxicological Summary for: Perfluorohexane sulfonate. Health Risk Assessment Unit, Environmental Health Division. Link [https://www.health.state.mn.us/communities/environment/risk/docs/guidance/gw/pfhxs.pdf].

• NJ DWQI. (2015). Health-Based Maximum Contaminant Level Support Document: Perfluorononanoic Acid (PFNA). New Jersey Drinking Water Quality Institute Health Effects Subcommittee. Link [https://dep.nj.gov/pfas/standards/].

EPA Response: The EPA finds that the ATSDR minimal risk levels for PFHxS and PFNA currently represent the best available, peer-reviewed science for these chemicals. SDWA specifies that an agency action that is based on science must use "the best available, peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices." At this time, the 2021 *ATSDR Toxicological Profile for Perfluoroalkyls*, which covers 10 PFAS including PFHxS and PFNA, represents the best available peer-reviewed scientific information on the human health effects of PFHxS and PFNA. ATSDR minimal risk levels for PFHxS and PFNA are appropriate for use under SDWA because ATSDR uses scientifically credible approaches, its work is internally and externally peer-reviewed and undergoes public comment, and its work represents the current best available science for these two chemicals. The 2021 *ATSDR Toxicological Profile for Perfluoroalkyls* underwent intra- and interagency review and subsequent external peer review by seven experts with knowledge of toxicology, chemistry, and/or health effects. The EPA notes that the state assessments suggested by the commenter pre-date the 2021 ATSDR toxicological profile for PFAS. See also section 4.3.3 of this *Response to Comments* document.

Michigan Department of Environment, Great Lakes, and Energy (EGLE) Drinking Water and Environmental Health Division (DWEHD) (Doc. #1597, SBC-042975)

In the case of PFBS and PFNA, Michigan established 2020 MCLs of 420 ng/l and 6 ng/l respectively, initially proposed by an independent panel of scientists.1 [REF1: Health-Based Drinking Water Value Recommendations for PFAS in Michigan, a Report by the Michigan Science Advisory Workgroup, July 2019.] These recommendations were developed based on a thorough review of the best available peer-reviewed scientific studies at the time and utilized in EGLE's subsequent rulemaking efforts. As these MCLs are below the MCLGs proposed by EPA in the NPDWR, EGLE DWEHD asks EPA to consider these lower values for calculating its proposed MCLGs/MCLs.

EPA Response: The EPA followed its guidance and process to determine MCLGs for PFBS and PFNA based on the best available, peer-reviewed science. Please see sections 4.3.1, 4.3.2, and 4.3.3 of the EPA response in this *Response to Comments* document, and please also see the Hazard Index MCLG support document for a complete description of MCLG derivation for PFBS and PFNA (USEPA, 2024h). The EPA notes that the state assessment suggested by the commenter pre-dates the EPA's PFBS toxicity assessment (USEPA, 2021d) and the 2021 ATSDR toxicological profile for PFAS (ATSDR, 2021). See also section 4.3.3 of the EPA response in this *Response to Comments* document.

PFBS

Washington State Department of Health (DOH) (Doc. #1665, SBC-044411)

EPA requests comment on the derivation of the HBWCs for each of the four PFAS considered as part of the HI.

PFBS

• DOH concurs with the RfD, but request EPA consider infants when selecting the drinking water intake rate for the PFBS Health-Based Water Concentration. Infants should be considered a sensitive life stage since neonatal thyroid function also supports infant growth and neurodevelopment. [FN3: Miller, M.D., et al., Thyroid-disrupting chemicals: interpreting upstream biomarkers of adverse outcomes. Environ Health Perspect, 2009. 117(7): p. 1033-41.] [FN4: Coperchini, F., et al., Thyroid Disrupting Effects of Old and New Generation PFAS. 2021. 11(1077). 228.] [FN5: Min, H., et al., Maternal Hypothyroxinemia-Induced Neurodevelopmental Impairments in the Progeny. Mol Neurobiol, 2016. 53(3): p. 1613-1624.] Thyroid tissue stores of T4 are low in newborn children making them less able than adults to compensate for reductions in T4. [FN6: Van den Hove, M.F., et al., Hormone synthesis and storage in the thyroid of human preterm and term newborns: effect of thyroxine treatment. Biochimie, 1999. 81(5): p. 563-70.] Washington State included infants as a sensitive group for this endpoint and used the 95th percentile water intake rates for infants (birth to <1 year old) to protect the developing child (see Table below). Michigan and California risk assessors also used infant drinking water intake rates to derive their state regulations for PFBS in drinking water based on this same endpoint.

[Table 1: See docket ID: EPA-HQ-OW-2022-0114-1665]

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Environmental Working Group (EWG) (Doc. #1721, SBC-045417)

The EPA should lower the health-based water concentrations, especially for PFBS.

The EPA should maintain its hazard index approach for GenX, PFBS, PFHxS, and PFNA while also reassessing the toxicity values used to calculate the health-based water concentrations for each.

When developing an MCL, SDWA requires the EPA to consider not only health effects on the general population, but also "groups within the general population such as infants, children, pregnant women, the elderly, individuals with a history of serious illness, or other subpopulations that are identified as likely to be at greater risk of adverse health effects due to exposure to contaminants in drinking water."[FN64: 42 U.S.C. [sec] 300g–1(b)(3)(C)(i)(V) (requiring EPA to assess health impacts on greater-risk populations when establishing MCLs).] While the proposed rule includes a thorough accounting of health risks from the four HI PFAS, the analysis could be strengthened to include additional studies and considerations for vulnerable populations. Comments submitted by Earthjustice et al. include a detailed discussion of the science behind the HBWC calculation for each HI PFAS and suggests ways to strengthen each, particularly to better account for risks to sensitive populations like infants and children. [FN65: Earthjustice et al., supra note 7, at 21-27.]

In particular, the EPA should reassess and strengthen its proposed HBWC of 2000 ppt for PFBS. EPA's HBWC is significantly higher than the MCL of 420 ppt set by Michigan for PFBS in August 2020. [FN66: Michigan PFAS Action Response Team, Maximum Contaminant Levels (MCLs) https://www.michigan.gov/pfasresponse/drinking-water/mcl (last visited May 30, 2023).] It's also much higher than the notification level of 500 ppt adopted by California,[FN67: California Water Boards, PFAS: Per and Polyfluoroalkyl Substances, https://www.waterboards.ca.gov/drinking_water/certlic/drinkingwater/pfas.html (last updated March 16, 2023).] Washington state action level of 345 ppt,[FN68: Washington State Dep't of Health, PFAS, https://doh.wa.gov/community-and-environment/contaminants/pfas (last visited May 30, 2023).] and Minnesota's health-based guidance value of 100 ppt. [FN69: Minnesota Dep't of Health, PFAS and Health https://www.health.state.mn.us/communities/environment/hazardous/topics/pfashealth.html (last updated March 02, 2023).]

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

West Virginia Rivers Coalition et al. (Doc. #1746, SBC-052998)

[In particular, we strongly support their calls for EPA to:]

• Revise the Health-Based Water Concentration for PFBS to 240 ng/L

EPA Response: The EPA disagrees that the HBWC for PFBS should be revised to 240 ng/L. The commenter did not cite underlying data or rationale for the argument/factual assertion it made. Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-044835)

EPA's Toxicity Assessment for PFBS is Overly Conservative

Despite concerns about the relevance to human risk assessment, the HBWC for PFBS is based on changes in thyroid hormones in offspring of laboratory mice. [FN117: Feng X et al. Exposure of Pregnant Mice to Perfluorobutanesulfonate Causes Hypothyroxinemia and Developmental Abnormalities in Female Offspring. Toxicol Sci 155(2):409-419 (2017).] Although the elimination half-life is relatively short (estimated in humans at 25.8 to 44 days and in rodents to be only 4-5 hours), EPA's approach to estimating the human equivalent dose (HED) from the animal data relies on toxicokinetic (TK) data rather than using a traditional body-weight scaling. In light of the uncertainty over the volume of distribution and elimination half-life in humans, as detailed below, the use of the default allometric approach is more appropriate for estimating a HED. In addition, the HBWC includes a total uncertainty factor of 300, including an unnecessary UFD of 10, as discussed below. Reflecting these numerous uncertainties and EPA's conclusion that "[t]he overall confidence in the chronic RfD for thyroid effects is low," [FN118: USEPA. Human Health Toxicity Values for Perfluorobutane Sulfonic Acid (CASRN 375-73-5) and Related Compound Potassium Perfluorobutane Sulfonate (CASRN 29420-49-3). EPA/600/R-20/345F. Office of Research and Development (2021), at 4.] the Agency relies on this endpoint in calculating the HBWC.

The significance of changes in T4 levels in rodents to human risk assessment has been questioned by the National Academy of Sciences (NAS) [FN119: National Research Council. Health implications of perchlorate ingestion. Washington, DC National Academies Press. (2005). (NRC 2005). https://doi.org/10.17226/11202] and others because of the significant differences in binding proteins and affinities among species. In humans and other primates, thyroxine-binding globulin (TBG) is the principal protein that binds T4. [FN120: Dohler KD et al. The rat as model for the study of drug effects on thyroid function: Consideration of methodological problems. Pharmacol Ther 5(1-3):305-318 (1979).] Because of TBG's high affinity for T4, clearance of T4 from human serum is sharply reduced. Since TBG is not the primary carrier in adult rodents, most T4 in rodent serum is bound to albumin and transthyretin which have a binding affinity for T4 that is significantly lower than TBG. [FN121: USEPA PFBS Toxicity Assessment, at 83.] This difference contributes to a higher rate of T4 clearance in rodents which, in turn, contributes to the need for a higher rate of production of T4 per unit of body weight to maintain normal concentrations of T4. [FN122: Dohler et al. 1979.] Although EPA concludes that "significant differences in functional thyroid reserve capacity between human and rodent neonates are not

anticipated," the difference in T4 quantities in neonates [FN123: USEPA Final PFBS Toxicity Assessment, at 84.] suggests a need for caution in interpreting the rodent data.

These differences in binding proteins, binding affinities of the proteins for the hormones, turnover rates of the hormones, and thyroid stimulation suggest important quantitative differences between rodents and humans. NAS concludes, therefore, that –

[t]he committee does not agree that transient changes in serum thyroid hormone or TSH concentrations are adverse health effects; they are simply biochemical changes that might precede adverse effects. [FN124: Ibid, at 13]

In deriving the oral reference dose, EPA's final assessment uses a dose adjustment factor for estimating the HED despite the absence of information on clearance values. The Agency also acknowledges a nearly two-fold difference in the estimate of elimination half-live for PFBS (25.8 vs 44 days) but chooses the longer of the estimate in generating the HED. In light of the uncertainty in the data-derived extrapolation, use of the default body weight3/4 method is more appropriate for deriving the reference dose for PFBS. [FN125: USEPA. Guidance for applying quantitative data to develop data-derived extrapolation factors for interspecies and intraspecies extrapolation. EPA/100/R-14/002F. Risk Assessment Forum (2014).]

The analysis also applies a benchmark response (BMR) of a standard deviation (SD) of 0.5, based on the fact that the observed effects are "occurring in a sensitive life stage." [FN126: USEPA Final PFBS Toxicity Assessment, at 74.] According to its BMD guidance, however, a BMR of 1 SD is appropriate in the absence of information regarding the level of change that is considered biologically significant when assessing continuous data.

EPA's HBWC also includes a UFD of 10 based on concerns about developmental effects, particularly neurodevelopmental effects, the lack of chronic studies, and the absence of studies on immunotoxicity and mammary gland development. For PFBS, robust data are available on reproductive and developmental effects, including both a prenatal toxicity study and a two-generation reproduction study. Moreover, that developmental effects appear to be "less sensitive than thyroid hormone perturbations in developing mice" [FN127: USEPA Draft PFBS Toxicity Assessment, at 60.] Consequently, a toxicity value that protects against effects on thyroid hormones also will protect against developmental effects, particularly effects on neurodevelopment since EPA's stated concern is that perturbations in thyroid hormones may trigger neurodevelopmental effects. [FN128: It may also be possible to extrapolate from neurodevelopmental results results for PFHxS reported by Ramhoj et al.] After pointing out the connection between thyroid hormones and neurodevelopment, EPA provides no rationale for why neurodevelopmental effects should then be considered separately. Recent results from Ramhoj et al. who reported "no evidence of thyroid hormone-mediated neurobehavioral disruption in offspring" [FN129: Ramhoj et al. 2020.] after exposure to PFHxS may provide additional evidence for dropping the UFD based on concerns about neurodevelopmental effects.

EPA provides no rationale for the concern about mammary gland development other than a single reference to a study of mice exposed to PFOA. Effects on mammary glands in offspring,

moreover, were not reported in the prenatal toxicity and two-generation reproduction studies available for PFBS. The Agency's concern for the potential immunotoxicity of PFBS is based entirely on suggestions of immunotoxicity for other PFAS. In explaining the addition of the UFD, the Agency suggests that "immunotoxicity is an effect of increasing concern across several members of the larger PFAS family." In light of the limited amount of information on immune effects for PFBS, a UFD of 3 appears much more appropriate than the excessive factor of 10 used by the Agency.

EPA Response: The EPA disagrees with these comments. As noted in section 4.3.3 of the EPA response in this *Response to Comments* document, confidence in the critical study (Feng et al., 2017) and corresponding thyroid hormone critical effect in newborn mice was rated by the EPA as 'High;' this rating was a result of systematic study evaluation and risk of bias analysis by a team of the EPA experts. The Feng et al. (2017) study, the critical effect of thyroid hormone disruption in offspring, dose-response assessment, and corresponding RfD were subjected to extensive internal EPA, interagency, and public/external peer review. While confidence in the critical study was rated 'High,' the 'Low' confidence rating for the PFBS chronic RfD was in part a result of the lack of a chronic exposure duration study in any mammalian species; this lack of a chronic duration study was one of the considerations that resulted in the EPA applying a UF of 10 to account for database limitations (UF_D). Based on the EPA's human health assessment practices, the lowest confidence rating across the areas of consideration (e.g., existent hazard/dose-response database) is assigned to the corresponding derived reference value (e.g., RfD). Thus, the EPA has high confidence in the critical study (Feng et al., 2017) and critical effect/thyroid endpoint, but the database is relatively limited. Although the PFBS RfD was based on best available science, there is uncertainty as to the hazard profile associated with PFBS after prolonged (e.g., lifetime) oral exposure. In the toxicity assessment for PFBS (USEPA, 2021d), the EPA noted data gaps in specific health effects domains, as Is standard practice. Toxicity assessments for most chemicals identify data gaps; the issue of uncertainty due to toxicological study data gaps is not unique to PFBS. Data gaps are considered when selecting the UF_D because they indicate the potential for exposure to lead to adverse health effects at doses lower than the POD derived from the assessment's critical study. There is a potential that effects with greater dose-response sensitivity (i.e., occurring at lower daily oral exposures) might be discovered from a chronic duration exposure study. Due to this uncertainty, the EPA applied a UF_D of 10. Further, at the time the PFBS chronic RfD was developed, there were indeed indications from other structurally related PFSAs (e.g., PFOS) that more specialized health outcome domains, such as immunotoxicity, may be significantly more sensitive than other domains traditionally evaluated in repeat-dose studies (e.g., organ weights, histopathology, clinical chemistry, etc.). As such, in the absence of information as to the immunotoxicity potential of PFBS, this was also considered a data gap that warranted additional uncertainty. This is also true of some developmental endpoints such as mammary gland development (and anogenital distance) which is often observed on the lower end of dose-response(s) in many single- and/or multi-generation repro/dev studies. Unfortunately, an available two-generation reproductive/developmental toxicity study in rats available for PFBS (Lieder et al., 2009) did not include endpoints such as mammary gland

development in the evaluation of F1 or F2 pups. Therefore, the lack of data on endpoints that are known to be highly sensitive in repro/developmental studies, for those chemicals with endocrine disrupting activity, represents another data gap for PFBS which is why it was considered in the application of a UF_D of 10.

The EPA disagrees with the comment that the default allometric approach is more appropriate for estimating an HED. In human health risk assessment practice, the EPA considers a hierarchical approach to cross-species dosimetric scaling consistent with technical guidance to calculate HEDs (USEPA, 2011; see pp. X-XI of the Executive Summary in 'Recommended Use of Body $Weight^{3/4}$ as the Default Method in Derivation of the Oral Reference Dose'). The preferred approach is physiologically-based toxicokinetic (PBTK) modeling; however, there are rarely sufficient chemical-specific data to properly parameterize such a model. In the absence of a PBTK model, the EPA considers an intermediate approach in which chemical-specific data across species, such as clearance or plasma half-life, are used to calculate a DAF (USEPA, 2011). If chemical-specific TK data are not available, only then is a default approach used wherein allometric scaling, based on body weight raised to the ¾ power, is used to calculate a DAF. The human health toxicity assessment for PFBS invoked the intermediate approach, consistent with guidance, as TK data were available for humans and rodents.

Please see section 4.3.3 of this *Response to Comments* document for the EPA response to comments related to uncertainty factors.

Earthjustice et al. (Doc. #1808, SBC-053409)

ii. EPA Should Revise its HBWC for PFBS to 240 ng/L

EPA's highest, and least protective, HBWC is for PFBS, a chemical that is often "considered [as] a replacement for PFOS." [FN162: EPA, Drinking Water Health Advisories for PFAS Fact Sheet for Communities, at 2 https://www.epa.gov/system/files/documents/2022-06/drinking-water-ha-pfas-factsheet- communities.pdf.] EPA's proposed HBWC of 2000 ppt PFBS is significantly higher than toxicity values and drinking water standards adopted by California (500 ppt), Michigan (420 ppt), Washington (345 ppt), and Minnesota (100 ppt). [FN163; Cal. Water Boards, Notification Level Issuance, State Water Res. Control Bd. (Mar. 5, 2021), https://www.waterboards.ca.gov/drinking_water/certlic/drinkingwater/pfas.html; Mich. PFAS Action Response Team, Maximum Contaminant Levels (MCLs), https://www.michigan.gov/pfasresponse/drinking-water/mcl (last accessed May. 25, 2023); Wash. State Dep't of Health, Recommended State Action Levels for Per- and Polyfluoroalkyl Substances (PFAS) in Drinking Water: Approach, Methods, and Supporting Information (Nov. 1, 2021), https://doh.wa.gov/sites/default/files/2022-02/331-673.pdf; Minn. Dep't of Health, Per- and Polyfluoroalkyl Substances (PFAS) and Health, at 3–4 (Sept. 6, 2022), https://www.health.state.mn.us/communities/environment/hazardous/docs/pfashealth.pdf.]

In deriving a RfD for PFBS, EPA, California, Michigan and Washington used the same health effect (impaired thyroid development) and the same approach for calculating a human equivalent

dose, resulting in similar RfDs. [FN164: We support the use of a more chemical-specific dose adjustment factor in EPA's final toxicity assessment versus the allometric scaling performed in EPA's draft document.] However, EPA's PFBS Lifetime Health Advisory for drinking water, which serves as the foundation for EPA's proposed HBWC, deviated from state risk assessments most notably in the choice of DWI-BW (rate of water intake). In order to protect infants from harmful PFBS exposures, California, Michigan, and Washington selected a higher value for drinking water intake associated with infant drinking water consumption when deriving their drinking water limits for PFBS. [FN165: OEHHA, Notification Level Recommendation: Perfluorobutane Sulfonic Acid in Drinking Water, at 29–30 (Jan. 2021), https://oehha.ca.gov/media/downloads/water/chemicals/nl/pfbsnl121820.pdf; Wash. Dep't of Health, Recommended State Action Levels for Per- and Polyfluoroalkyl Substances (PFAS) in Drinking Water: Approach, Methods, and Supporting Information, Off. Of Pub. Health Sci., at 80– 81 (Nov. 1, 2021), https://doh.wa.gov/sites/default/files/2022-02/331-673.pdf.] EPA, on the other hand, relied on a lower water intake rate associated with "women of childbearing age" [FN166: EPA, EPA-822-P-23-004, Maximum Contaminant Level Goal (MCLG) Summary Document for a Mixture of Four Per- and Polyfluoroalkyl Substances (PFAS): HFPO-DA and its Ammonium Salt (also known as GenX Chemicals), PFBS, PFNA, and PFHxS, Off. Of Water, at 12 (Mar. 2023), https://www.regulations.gov/document/EPA-HQ-OW-2022-0114-0906.] and thus failed to address PFBS' increased risks to infants, a "potentially susceptible life stage[] for the types of effects observed in animal testing with PFBS." [FN167: Wash. Dep't of Health, Recommended State Action Levels for PFAS, at 79.] Thus, EPA's HBWC for PFBS falls short of protecting one of the most "sensitive population(s) or life stage(s) (i.e., those that may be more susceptible or sensitive to a chemical exposure)." [FN168: EPA, MCLG Summary Document for a Mixture of Four PFAS, at 5.]

The thyroid harm identified by EPA resulted from decreased serum levels of T4 from PFBS exposure during a developmental life stage, effects that begin prenatally and continue into infancy. Decreased levels of T4 indicate dysfunction or underdevelopment of the thyroid gland. While a decrease in T4 affects the pregnant mice, those effects can also carry over to their offspring and "persist[] until the pubertal and adult periods." [FN169: Xuejiao Feng et al., Exposure of Pregnant Mice to Perfluorobutanesulfonate Causes Hypothyroxinemia and Developmental Abnormalities in Female Offspring, 155 Toxicological Sciences, 409, 417 (2017), https://doi.org/10.1093/toxsci/kfw219.] The authors of the study that EPA relied upon concluded that PFBS "may impair thyroid development in offspring, leading to permanent hypothyroxinemia" [FN170: Id. At 414.] Infants with hypothyroxinemia experience impaired growth and development because the thyroid orchestrates processes that are critical to their growth, including brain development. Thus, many infants with hypothyroxinemia experience intellectual disabilities and growth failures that require treatment through puberty and, in some cases, into adulthood. [FN171: See generally Noora Moog et al., Influence of Maternal Thyroid Hormones During Gestation on Fetal Brain Development, 342 Neuroscience 68, 68–100 (2017), https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4819012/; Stanford Medicine, Congenital Hypothyroidism in Children, Childrens Health,

https://www.stanfordchildrens.org/en/topic/default?id=hypothyroidism-in-children-90-P01963.] While women of childbearing age are sensitive to developmental toxicity and persistent changes in thyroid hormone levels associated with PFBS, maternal thyroid hormones play a critical role in fetal and infant growth and neurodevelopment. Thyroid development and stores of T4 are especially important in infants whose T4 stores are lower and not as capable of offsetting declines. [FN172: Francesca Coperchini et al., Thyroid Disrupting Effects of Old and New Generation PFAS, 11 Frontiers in Endocrinology Art. No. 612320 (2021), https://www.ncbi.nlm.nih.gov/pmc/articles/PMC7851056/; Hui Min et al., Maternal Hypothyroxinemia-Induced Neurodevelopmental Impairments in the Progeny, 53 Molecular Neurobiology 1613, 1613–1624 (2016), https://pubmed.ncbi.nlm.nih.gov/25666160/; Miller, M.D., et al., Thyroid-Disrupting Chemicals: Interpreting Upstream Biomarkers of Adverse Outcomes, 117 Env't Health Persp. 1033, 1033–41 (2009), https://pubmed.ncbi.nlm.nih.gov/19654909/.] Drinking water intake is a pertinent exposure factor that is "intended to protect sensitive populations and life stages within the general population from adverse effects." [FN173: EPA, Drinking Water Health Advisory: Perfluorobutane Sulfonic Acid Potassium Perfluorobutane Sulfonate, at 18.] EPA's failure to consider the increased drinking water intake of infants understates the exposure to PFBS and its health effects on a sensitive population. EPA's HBWC may provide protections for adults and fetuses but it ignores the risks that PFBS poses for infants and does not address "adverse effects can result from short or intermittent exposure during a critical period of development." [FN174: Id. At 17 (citing EPA, EPA/600/FR-91/001, Guidelines for Developmental Toxicity Risk Assessment, (Dec. 5, 1991), https://www.epa.gov/sites/default/files/2014-11/documents/dev_tox.pdf).]

Using the DWI-BW listed on Table 3 of the Drinking Water Health Advisory for PFBS [FN175: EPA, Drinking Water Health Advisory: Perfluorobutane Sulfonic Acid and Perfluorobutane Sulfonate, at 19.] for formula fed infants (0.249 L/kg/day), the HBWC for PFBS should be no more than 240 ng/L.

HBWC = (RfD/DWI-BW)*RSC

= ((0.0003 mg/kg-bw/day) / (0.249 L/kg-bw/day)) *0.2

= 0.00024 mg/L = 240 ng/L

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Mississippi Farm Bureau Federation (Doc. #1826, SBC-044267)

May 30, 2023

Alexis Lan

Office of Ground Water and Drinking Water Environmental Protection Agency

1200 Pennsylvania Avenue NW Washington, DC 20460

Dear Ms. Lan,

On behalf of the Mississippi Farm Bureau Federation (MFBF), I appreciate this opportunity to submit comments and concerns in response to Docket ID No. EPA-HQ-OW-2022-0114, Per- and Polyfluoroalkyl Substances National Primary Drinking Water Regulation. MFBF is a general agricultural organization representing over 180,000 farm families. Mississippi has approximately 300 municipal water supplies and over 800 rural water systems. The vast majority of our members live in rural communities and will be significantly impacted by the proposed regulations. Our comments here will be brief, but We urge you to please give special consideration to the more substantive comments submitted by the American Farm Bureau Federation on this important proposed rule.

MFBF supports safe and clean drinking water supplies and understands EP''s urgency to begin understanding and addressing the potential health effects of PFAS. As EPA moves forward, we are concerned that there is insufficient data on human health effects from some PFAS to support the ultra-low maximum concentration limits proposed. While we are confident that there is good scientific data around the longer 8-9 chain carbon PFAS, we are concerned that the agency may be""assumin"" similar health risk from the shorter (3-4 chain carbon) PFAS.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document. The EPA did not assume that health risks for PFBS (the 4-carbon PFAS being regulated in this action) are similar to those of PFOA and PFOS (8-carbon PFAS). Rather, the agency conducted a separate toxicity assessment for PFBS based on experimental animal toxicological data for PFBS. The toxicity assessment was reviewed internally by EPA scientists, federal partners, external peer reviewers, and the public (USEPA, 2021d).

PFHxS

American Water Works Association (AWWA) (Doc. #1759, SBC-045582)

PFHxS

As part of the proposal, EPA has developed a HBWC using minimal risk levels that were developed by the Agency for Toxic Substances and Disease Registry (ATSDR) (ATSDR, 2021). AWWA supports the use of the proposed HBWC as a screening level for PFHxS in support of the regulatory determination as EPA's Integrated Risk Information System (IRIS) program works towards completing its health assessment (EPA, 2023b).

EPA Response: The commenter agrees with the EPA's approach.

Washington State Department of Health (DOH) (Doc. #1665, SBC-052893)

PFHxS

• WA concurred with state health risk assessors in Michigan in selecting Minnesota Department of Health's RfD of 9.7 ng/kg-day for PFHxS as the base for our state action on PFHxS. We think this is a better basis for the HBWC than the ATSDR MRL.

• The Minnesota Department of Health derived their RfD from a study by the National Toxicology Program (NTP) 2019. Specifically, a 28-day oral gavage study in adult male and female Harlan Sprague Dawley rats. The study measured growth and gross behavior, serum hormone levels, and evaluated all organs for gross and histopathological findings at the end of 28 days. Serum measurements of PFHxS were collected for assessment of internal dose at the end of the experiment. There was a dose-dependent decrease in serum thyroid hormone levels in both sexes with more marked reductions in T3, fT4 and tT4 in male [FN7: National Toxicology Program, NTP Technical Report on the Toxicity Studies of Perfluoroalkyl Sulfonates (Perfluorobutane Sulfonic Acid, Perfluorohexane Sulfonate Potassium Salt, and Perfluorooctane Sulfonic Acid) Administered by Gavage to Sprague Dawley Rats 2019, U.S. Department of Health and Human Services: Research Triangle Park, NC].

• These study results were supported by Ramhøj et al. 2018 experiments in pregnant Wistar rats. Oral administration of PFHxS produced marked, dose-dependent reductions in serum total T4 in pregnant and lactating dams and in pups [FN8: Ramhøj, L., et al., Perfluorohexane Sulfonate (PFHxS) and a Mixture of Endocrine Disrupters Reduce Thyroxine Levels and Cause Antiandrogenic Effects in Rats. Toxicol Sci, 2018. 163(2): p. 579-591.].

• WA also considered infants a sensitive group for thyroid hormone reduction (see reasons above under PFBS) and we encourage EPA to pair this lower RfD with a translactational exposure model that accounts for higher exposures of breastfed infants. In our model based on Goeden et al. 2019, infants had more than twice the PFHxS serum concentration of their mothers after breast-feeding exclusively for 6 months and then tapering their breastmilk consumption while introducing foods over the following 6 months.

EPA Response: The EPA disagrees with this comment. At this time, the 2021 ATSDR toxicological profile represents the best available peer-reviewed scientific information regarding the human health effects of PFHxS. The EPA used a chronic toxicity reference value for PFHxS of 2.0 ng/kg/day, which is slightly lower (more health-protective) than the RfD used in the Minnesota Department of Health's analysis (9.7 ng/kg-day). Additionally, the 2021 ATSDR minimal risk level is more current than the Minnesota Department of Health's analysis.

For information about DWI-BW selection, please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Massachusetts Department of Environmental Protection (MassDEP) (Doc. #1726, SBC-052977)

PFHxS Health-Based Water Concentrations

EPA appears to have an error in the calculation of the PFHxS HBWC in the Mixture document (Section 2.4.4, pages 16-17). The chronic reference value of 2x10-6 mg/kg-day divided by the

DWI-BW of 0.034 L/kg-day times the RSC of 0.2 should yield a value of 12 ng/L, not 9.2 ng/L rounded to 9 ng/L. The PFHxS HBWC should be corrected to reflect the values included in the document.

EPA Response: The agency has corrected the value in the final NPDWR. The correct HBWC for PFHxS is 10 ng/L (ppt).

U.S. Chamber of Commerce et al. (Doc. #1713, SBC-053336)

In addition to the highly uncertain toxicity value, and the overly conservative RSC, EPA also appears to have erred in its calculation of the HBWC for PFHxS. Based on the inputs provided in the formula (which, as noted above, we do not support), the derived HBWC should be 12 ppt, not 9 ppt [FN27: U. S. EPA. Maximum Contaminant Level Goal (MCLG) Summary Document for a Mixture of Four Per- and Polyfluoroalkyl Substances (PFAS): GenX Chemicals, PFBS, PFNA and PFHxS, 2023, EPA–822–P–23–004, at pages 16-17, available at: https://www.epa.gov/system/files/documents/2023-03/PFAS%20HI%20MCLG%20Public%20Review%20Draft%2009%20March%202023.pdf.].

EPA Response: The agency has corrected the value in the final NPDWR. The correct HBWC for PFHxS is 10 ng/L (ppt).

Connecticut Department of Public Health (CT DPH) (Doc. #1745, SBC-052992)

CT DPH reviewed the following language“”The HBWC for PFNA is derived using a chronic reference value based on an ATSDR intermediate-duration oral Minimal Risk Level, which was based on developmental effects seen in mice after oral PFHxS exposure (ATSDR, 2021”” and“”As further described in USEPA (2023a), the HBWC for PFNA is calculated to be 100 pp”” regarding the HBWC for PFNA. USEPA should make the following corrections: 1)“”oral PFHxS exposur”” in the first sentence should be“”oral PFNA exposur””; 2)“”100 pp”” in the second sentence should be“”10.0 pp””.

EPA Response: The agency has corrected the PFHxS HBWC value in the final NPDWR. The correct HBWC for PFHxS is 10 ng/L (ppt) and it is derived using a chronic toxicity reference value based on a minimal risk level based on developmental effects seen in mice after oral PFNA exposure.

Connecticut Department of Public Health (CT DPH) (Doc. #1745, SBC-052989)

4. EPA requests comment on the derivation of the HBWCs for each of the four PFAS considered as part of the HI.

CT DPH reviewed the HBWC for PFHxS but was not able to reach the same value (9.0 ppt) following the described calculation. The RfD, 0.000002 mg/kg/day, divided by the DWI-BW of

0.034L/kg/d, multiplied by the RSC of 20% would be 1.18e-5 mg/L (i.e. 11.8 ppt). USEPA should better explain how the 9.0 ppt was reached or correct the value if it is a miscalculation.

EPA Response: The agency has corrected the value in the final NPDWR. The correct HBWC for PFHxS is 10 ng/L (ppt).

West Virginia Rivers Coalition et al. (Doc. #1746, SBC-045257)

[In particular, we strongly support their calls for EPA to:]

• Revise the Health-Based Water Concentration for PFHxS to 2 ng/L

EPA Response: The EPA disagrees that the HBWC for PFHxS should be revised to 2 ng/L. The commenter did not cite underlying data or rationale for the argument/factual assertion it made. Please see additional information in section 4.3.3 of the EPA response in this *Response to Comments* document.

City of Thornton, Colorado (Doc. #1748, SBC-044793)

Thornton requests that the EPA reevaluate the HBWC for PFHxS and increase if possible. Data from Colorado utilities with PFAS treatment in-place indicate that PFHxS breaks through treatment processes before other PFAS compounds. Because of the concentrations in Colorado waters, many utilities may have to replace their treatment media to meet the HI MCL while that media is still protective of the higher risk PFOA/PFOS compounds leading to increased and unnecessary costs.

EPA Response: The EPA disagrees. Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Earthjustice et al. (Doc. #1808, SBC-053408)

i. EPA Should Revise its HBWC for PFHxS to 2 ng/L

When calculating its HBWC for PFHxS, EPA relied on a RfD derived by ATSDR for thyroid follicular cell damage in adult male rats from a study by Butenhoff et al. [FN151: See ATSDR 2021 at 21, A54–A57 (citing John L. Butenhoff et al., Evaluation of Potential Reproductive and Developmental Toxicity of Potassium Perfluorohexanesulfonate in Sprague Dawley Rats, 27 Reprod. Toxicology 331, 331–334 (June 2009)).] However, in March 2022, OEHHA published a risk assessment analysis for PFHxS as part of its Notification Level Recommendation for PFHxS in Drinking Water. [FN152: OEHHA, Notification Level Recommendation: Perfluorohexane Sulfonic Acid in Drinking Water (Mar. 2022), https://oehha.ca.gov/media/pfhxsnl031722.pdf.] In its analysis, OEHHA evaluated the same studies as ATSDR and a newer toxicological study by the National Toxicology Program ("NTP"). [FN153: Id. at 15 (citing, inter alia, NTP, NTP Technical Report on the Toxicity Studies of Perfluoroalkyl Sulfonates (Perfluorobutane Sulfonic Acid, Perfluorohexane Sulfonate Potassium Salt, and Perfluorooctane Sulfonic Acid) (August

2019), https://cebs.niehs.nih.gov/cebs/publication/TOX-96)).] Ultimately, OEHHA derived Public Health-Protective Concentrations (equivalent to EPA's health-based water concentrations) for three sensitive endpoints because they occur in different populations. [FN154: Id. at 30.] In contrast, ATSDR only derived a single RfD. The analysis of multiple sensitive endpoints in deriving a final drinking water value is critical to ensure protection from all adverse health effects in all populations.

First, choosing the lowest human equivalent dose ("HED") to derive a RfD does not guarantee that the RfD will protect against all health effects. A less sensitive HED could reasonably result in a lower RfD due to differences in study design and overall application of uncertainty. The IRIS PFAS assessments follow best practices in calculating organ-specific RfDs for multiple identified health effects. [FN155: See, e.g., EPA, Toxicological Review of Perfluorohexanoic Acid and Related Salts, at 5–28.] OEHHA also followed these best practices and derived RfDs for decreased thyroxine (T4) (which is associated with thyroid toxicity) in adult male rats, decreased litter size in female mice, and increased relative liver weight in female rats. [FN156: OEHHA, Notification Level Recommendation: Perfluorohexane Sulfonic Acid in Drinking Water, at 26.] Whereas the lowest HED was for decreased litter size, the lowest RfD was identified as decreased total T4 due to the application of different uncertainty factors to the two outcomes. [FN157: Id. at 28.]

Secondly, choosing the lowest RfD to derive an HBWC does not guarantee that all health effects will be protected against. The influence of population specific drinking water exposure assumptions is also important to consider. In the case of OEHHA's analysis, the final health-protective concentration in drinking water was lowest for decreased T4 (2 ng/L), when protecting against possible health effects in infants. [FN158: Id. at 28–29.]

In its analysis, OEHHA states, "[f]or PFHxS, there are no developmental studies of thyroid hormone levels in animals, and no mouse studies reporting T4 or T3 levels. Despite this uncertainty, the point of departure ("POD") for decreased T4 in male rats is a suitable candidate for PFHxS HPC derivation due to the severity of possible developmental consequences of decreased T4 in humans." [FN159: Id. at 26.] Therefore, because infants are a sensitive group for decreased total T4, OEHHA applied a 0- to 6-month infant DWI-BW of 0.237 L/kg/day to derive a health-based water concentration.

We strongly support OEHHA's health-protective approach to the lack of developmental data on thyroid hormone disruption for PFHxS. There is no reason to assume that this health effect is limited to an adult male population. Rather, when data are available, decreased T4 during development has been identified as a sensitive endpoint for other PFAS. Importantly, OEHHA and IRIS have argued that even though decreased thyroid hormone levels appear less severe than classical hypothyroidism and are not associated with increased levels of thyroid- stimulating hormone (TSH), decreased T4 is correlated with neurodevelopmental and cognitive deficits in children, highlighting the importance of protecting the developing fetus, infants, and children against PFAS exposure. [FN160: See id. at 20.]

The analysis by OEHHA indicates that a HBWC of 2 ng/L should be set to protect the most vulnerable and sensitive populations. Because that level is lower than the PQL of 3 ng/L, when calculating the hazard index for the purpose of establishing and monitoring compliance with the PFHxS MCL EPA should rely on the PQL, as opposed to EPA's currently proposed and under-protective HBWC. [FN161: Proposed Rule, 88 Fed. Reg. at 18,680. Although we strongly recommend EPA adopt the analysis conducted by OEHHA, we acknowledge and support EPA's choice to apply an additional UF of 10 to adjust for subchronic-to-chronic duration (i.e., UFS), per agency guidance. Id. at 18,645–46.]

EPA Response: The EPA disagrees. Please see section 4.3.3 of the EPA response in this *Response to Comments* document for comments related to how HBWCs were derived.

3M Company (Doc. #1774, SBC-045656)

The absence of necessary peer review resulted in EPA making substantive errors that could have been identified and addressed before publication of the Proposed Rule. For example, EPA's selection of reference values for the four PFAS for which it is now issuing a preliminary regulatory determination contains important technical errors, including reliance on standards or studies that have been discredited and fail to account for numerous uncertainty factors. The proposed NPDWR also contains a math error in calculating the HBWC for PFHxS that resulted in EPA proposing an HBWC of 9 ppt instead of 10 ppt.

EPA Response: The agency has corrected the value in this NPDWR. The correct HBWC for PFHxS is 10 ng/L (ppt). Also, the commenter appears to claim that the toxicity reference values for the four PFAS rely on "standards or studies that have been discredited" but the commenter does not specify to which standards and/or studies the commenter is referring. For EPA responses to comments related to the toxicity reference values for HFPO-DA, PFNA, PFHxS, and PFBS, and how HBWCs for these four PFAS were derived, please see section 4.3.3 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-053413)

The Relevance of Thyroid Hormone Changes in PFHxS Animal Studies is Uncertain

ATSDR bases its MRL for PFHxS on the results of a developmental toxicity study by Butenhoff et. al. [FN106: Butenhoff JL et al. Evaluation of potential reproductive and developmental effects of potassium perfluorohexanesulfonate in Sprague Dawley rats. Reprod Toxicol 27:331-341 (2009).] that reported thyroid effects (hypertrophy and hyperplasia of the follicular cells) in parental male rats treated with PFHxS for at least 42 days. The investigators noted that the observed changes in rats "are consistent with the known effects of inducers of microsomal enzymes where the hepatocellular hypertrophy results in a compensatory hypertrophy and hyperplasia of the thyroid." In light of this possible link to PPARα activation in the liver and the significant differences in thyroid function between rodents and humans, [FN107: Capen CC et al. Species differences in thyroid, kidney, and urinary bladder carcinogenesis. IARC Scientific

Publications 147:1-14 (1999).] there is some question about the relevance of the rat data to humans.

Although Butenhoff et al. do not report hormone levels, NTP reported decreases in thyroxine (T4) concentrations in a dose-response manner but not a consistent increase in thyroid stimulating hormone (TSH). Nor does the NTP study report any histopathologic changes in the thyroid gland. [FN108: NTP. Technical Report on the Toxicity Studies of Perfluoroalkyl Sulfonates (Perfluorobutane Sulfonic Acid, Perfluorohexane Sulfonate Potassium Salt, and Perfluorooctane Sulfonic Acid) Administered by Gavage to Sprague Dawley (Hsd:Sprague Dawley SD

) Rats. Toxicity Report 96 (2019). (NTP TR-96).] The report notes that the decrease in thyroid hormones may be related to the activation of PPARα and CAR that could accelerate degradation of thyroxine by the liver. In a study conducted by Chang et al. no alterations in TSH were observed in mice administered PFHxS prior to mating and during mating, gestation, and lactation; nor were there histological alterations in the thyroid gland of the animals. [FN109: Chang S et al. 2018. Reproductive and developmental toxicity of potassium perfluorohexanesulfonate in CD-1 mice. Reprod Toxicol 78:150-168 (2018).] These results are consistent with those of Ramhoj et al. who found that ”PFHxS lowered thyroid hormone levels in both dams and offspring in a dose-dependent manner, but did not change TSH levels, weight, histology, or expression of marker genes of the thyroid gland.” [FN110: Ramhoj L et al. Evaluating thyroid hormone disruption: investigations of long-term neurodevelopmental effects in rats after perinatal exposure to perfluorohexane sulfonate (PFHxS). Sci Rep 20:2672 (2020).]

The ATSDR MRL is based on a NOAEL of 1 milligram per kilogram per day (mg/kg-day) and a total uncertainty factor for 300, including a UFD of 10. To calculate the HBWC, EPA applied an additional UFS of 10. According to ATSDR, the decision to add a UFD of 10 is based on the limited number and scope of the available studies and the absence of information on immunotoxicity.

According to EPA guidance, a UFD is typically and properly applied in the absence of reproductive and developmental information. EPA’s guidance explains that a UFD is applied when reproductive and developmental toxicity studies are missing since they have been found to provide valuable information for establishing a LOAEL. [FN111: Dourson ML et al. (1996) Evolution of science-based uncertainty factors in noncancer risk assessment. Regul Toxicol Pharmacol 24:108–120 (1996).] The lack of a two-generation study for PFHxS would justify the use of a 3-fold uncertainty factor, based on EPA guidance. Any concerns about early life sensitivity are addressed by Chang et al. who report no treatment-related effects on postnatal survival of development in offspring exposed in utero through PND 36 and more recently by Ramhoj et al. (2020) who followed maternal exposure from early gestation (GD7) through lactation (PND22), and then again followed up after 4–5 months of age for the F1 females and 8–

9 months for the F1 males.. Although limited, Butenhoff et al. do not report evidence of immunotoxicity in rats exposed to up to 10 mg/kg per day by gavage for up to 56 days.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

PFNA

American Water Works Association (AWWA) (Doc. #1759, SBC-045586)

PFNA

As with PFHxS, EPA also developed a HBWC for PFNA using data from ATSDR (ATSDR, 2021). AWWA supports the use of the proposed HBWC as a screening level for PFNA to guide this determination in the absence of a completed IRIS program health assessment (EPA, 2023b).

EPA Response: The commenter agrees with the EPA's approach.

Washington State Department of Health (DOH) (Doc. #1665, SBC-052897)

PFNA

• Consider amending the ATSDR MRL to account for a more recent estimate of serum half-life published after the ATSDR MRL: Yu, C.H., et al., Biomonitoring: A tool to assess PFNA body burdens and evaluate the effectiveness of drinking water intervention for communities in New Jersey, Int J Hyg Environ Health, 2021. 235: p. 113757. Yu et al. 2021 published a three-year biomonitoring study in a New Jersey community exposed to elevated PFNA in their drinking water. The geometric mean of the study group was five times higher than the mean PFNA levels in U.S. adults as measured in 2015-2016 by the CDC. The study collected three blood samples one year apart in 99 participants from 2017 to 2020. Residents ranged in age between 20 – 74 years old and were 68 percent female. Half-life estimates of PFNA in serum were 3.52 years for the 68 most highly exposed participants. DOH suggest that EPA consider the PFNA serum halflife in the more highly exposed members to minimize bias from ongoing background exposure to PFNA. Modifying the ATSDR MRL with the new half-life estimate of 3.52 years (1,285 days) from Yu et al. 2021, would result in:

• MRL (mg/kg-day) = POD (mg/L) x DAF (L/Kg-day) ÷ UF

o POD = 6.8 mg/L PFNA in serum

o DAF = Vd x (Ln(2)/T1/2) = 0.2 L/kg x (Ln(2)/1,285 days) =1.08 x 10-4 L/kg – day.

o UF = 300

• MRL = = 6.8 mg/L x 1.08 x 10-4 L/kg – day ÷ 300 = 2.45 x10-6 mg/kg-day (or 2.5 ng/kg-day)

EPA Response: The EPA disagrees with this comment. The EPA does not have authority to revise an ATSDR minimal risk level. Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

West Virginia Rivers Coalition et al. (Doc. #1746, SBC-052999)

[In particular, we strongly support their calls for EPA to:]

• Revise the Health-Based Water Concentration for PFNA to 2 ng/L

EPA Response: The EPA disagrees that the HBWC for PFNA should be revised to 2 ng/L. The commenter did not cite underlying data or rationale for the argument/factual assertion it made. Please see additional information in section 4.3.3 of the EPA response in this *Response to Comments* document.

Earthjustice et al. (Doc. #1808, SBC-053410)

iii. EPA Should Revise its HBWC for PFNA to 2 ng/L

In deriving a health-based water value for PFNA from ATSDR's RfD, EPA chose the drinking water intake estimate for lactating women (0.0469 L/kg-bw/day). [FN176: EPA, MCLG Summary Document for a Mixture of Four PFAS, at 15.]

However, the critical effects selected by ATSDR (decreased body weight and developmental delays including delayed eye opening, preputial separation and vaginal opening) occur during development. [FN177: Id. at 13.] Furthermore, a transgenerational toxicokinetic model for PFNA has been developed and used by some states which demonstrates a significantly higher level of exposure for breastfed infants. [FN178: Wash. Dep't of Health, Recommended State Action Levels for PFAS, at 21–24.] We recommend that EPA either evaluate and use this transgenerational toxicokinetic model or apply a drinking water intake rate for infants. Using the drinking water intake rate for formula fed infants (0.249 L/kg-bw/day) (see above), the health-based value goal for PFNA should be no more than 2 ng/L.

HBWC = (RfD/DWI-BW)*RSC

= ((0.000003 mg/kg-bw/day) / (0.249 L/kg-bw/day)) * 0.2

= 0.0000024 mg/L = 2 ng/L

The HBWC for PFNA should be no higher than 2 ng/L to protect the most vulnerable and sensitive populations. Because that level is lower than the PQL of 4 ng/L, when calculating the hazard index for the purpose of establishing and monitoring compliance with the PFNA MCL, EPA should rely on the PQL, as opposed to EPA's currently proposed and under-protective HBWC. [FN179: Proposed Rule, 88 Fed. Reg. at 18,680.]

EPA Response: The EPA disagrees. To select an appropriate DWI-BW for use in derivation of the HBWC for PFNA, the EPA considered the PFNA exposure interval used in the oral reproductive/developmental toxicity study in mice that served as the basis for chronic RfD derivation (the critical study). In this study, decreased body weight gain and impaired development (i.e., delayed eye opening, delayed sexual maturation) were observed in mice born to mothers that were orally exposed to PFNA during gestation (with presumed continued indirect exposure of offspring via lactation). This exposure window corresponds to three potentially sensitive human adult life stages that may represent critical windows of PFNA exposure: women of childbearing age, and pregnant women, and lactating women (Table 3-63 in USEPA, 2019). Of these three, the highest DWI-BW, for lactating women (0.0469 L/kg/day), is anticipated to be protective of the other two sensitive life stages and was used to calculate the HBWC for PFNA. Please see section 4.3.3 of the EPA response in this *Response to Comments* document for further discussion of how DWI-BWs were selected.

American Chemistry Council (ACC) (Doc. #1841, SBC-052930)

Developmental Effects Associated with PFNA Exposure are Not Relevant to Humans

ATSDR's intermediate MRL is based on reports of decreased body weight gain and developmental delays in the offspring of mice administered PFNA via gavage in a study by Das et al. [FN112: Das KP et al. Developmental toxicity of perfluorononanoic acid in mice. Reprod Toxicol 51:133-144 (2015).] These effects occurred concomitant with maternal toxicity and therefore, according to governing EPA guidelines, should not be used as the critical effect. [FN113: USEPA Developmental Toxicity Guidelines, at 6.] Moreover, Wolf et al. [FN114: Wolf CJ et al. Developmental effects of perfluorononanoic acid in the mouse are dependent on peroxisome proliferator-activated receptor-alpha. PPAR Res 2010 10.1155/2010/282896 (2010).] did not report changes in pup body weight or postnatal development in PPARα-null mice at 2 mg/kg- day, suggesting that these effects are rodent-specific responses to PFNA mediated by PPARα with little to no relevance to humans. [FN115: It appears that EPA as reviewed the available thyroid data as part of its ongoing IRIS assessment for PFNA but has not made the results of that review available as part of this rulemaking. See USEPA IRIS Handbook, at 5-18.] Reported liver effects in mice exposed to PFNA also may result from PPARα activation of limited relevance to humans.

In addition to concerns about study selection, ATSDR's decision to include a 10-fold UFD based on the limited and scope number of studies examining PFNA toxicity is unjustified. In particular, ATSDR suggests that reproductive toxicity may be a more sensitive endpoint than developmental toxicity and that data on immune function are lacking. [FN116: ATSDR PFAS Tox Profile, at A-66.] In the case of PFNA, developmental toxicity data do exist which suggest that effects are the result of PPARα activation. As noted by ATSDR, epidemiology studies examining a possible association between serum PFNA and immunosuppression or hypersensitivity have been negative or mixed. While animal data are lacking, existing human data do not suggest the potential for immune effects. Consequently, a UFD of 3 seems more appropriate given only the lack of data

on reproductive effects and acknowledging the existence of data on developmental and immune effects.

EPA Response: The EPA disagrees with this comment. Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

HFPO-DA (GenX Chemicals)

Earthjustice et al. (Doc. #1808, SBC-053411)

iv. EPA Should Revise its HBWC for GenX to 2 ng/L

EPA finalized the Human Health Toxicity Assessment for GenX in October 2021. [FN180: See EPA, Human Health Toxicity Values for Hexafluoropropylene Oxide (HFPO) Dimer Acid and Its Ammonium Salt (CASRN 13252-13-6 and CASRN 62037-80-3), Also Known as 'GenX Chemicals at 86-88 (Oct. 2021), https://www.epa.gov/system/files/documents/2021-10/genx-chemicals-toxicity-assessment_tech-edited_oct-21-508.pdf. We support the changes to the draft document that were made in response to the public comment process. Specifically, we support the NTP Pathology Working Group findings on liver lesions, which were based on more contemporary pathology guidelines than were used in prior analyses. We further support the application of a full uncertainty factor to account for the use of a study with less chronic exposure and a full uncertainty factor for database deficiencies.] In the development of the Lifetime Health Advisory for GenX, EPA "identified three potentially sensitive life stages for GenX chemical exposure—women of childbearing age (13 to < 50 years), pregnant women, and lactating women." [FN181: EPA, Drinking Water Health Advisory: Hexafluoropropylene Oxide (HFPO) Dimer Acid (CASRN 13252-13-6) and HFPO Dimer Acid Ammonium Salt (CASRN 62037-80-3), Also Known as 'GenX Chemicals, Off. of Water, at 21 (June 2022), https://www.epa.gov/system/files/documents/2022-06/drinking-water-genx-2022.pdf.] In setting its HBWC, EPA ultimately chose the drinking water intake estimate for lactating women, stating that this would be protective of the other two populations as well (i.e., pregnant women and women of childbearing age). [FN182: EPA, MCLG Summary Document for a Mixture of Four PFAS, at 9.] However, there is no analysis to suggest that infants and young children would be sufficiently protected from liver or other developmental effects due to exposure during this critical stage.

Furthermore, the NOAEL for developmental effects linked to GenX exposure is within the same range as the NOAEL for liver effects (i.e., within one order of magnitude). [FN183: EPA, Human Health Toxicity Values for Hexafluoropropylene Oxide (HFPO) Dimer Acid and Its Ammonium Salt (CASRN 13252-13-6 and CASRN 62037-80-3) Also Known as 'GenX Chemicals,' (Oct. 2021) https://www.epa.gov/system/files/documents/2021-10/genx-chemicals- toxicity-assessment_tech-edited_oct-21-508.pdf] We therefore recommend that EPA apply a DWI-BW for infants. Using the DWI-BW listed on Table 3 of the Drinking Water Health Advisory for GenX for formula-fed infants (0.249 L/kg/day), the health- based value goal for GenX should be no more than 2 ng/L.

HBWC = (RfD/DWI-BW)*RSC

= ((0.000003 mg/kg-bw/day) / (0.249 L/kg-bw/day)) *0.2

= 0.0000024 mg/L = 2 ng/L

The HBWC for GenX should be no higher than 2 ng/L to protect the most vulnerable and sensitive populations. Because that level is lower than the PQL of 5 ng/L, when calculating the hazard index for the purpose of establishing and monitoring compliance with the GenX MCL EPA should rely on the PQL, as opposed to EPA's currently proposed and under-protective HBWC . [FN184: Proposed Rule, 88 Fed. Reg. at 18,680.]

EPA Response: The EPA disagrees with this comment. Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

West Virginia Rivers Coalition et al. (Doc. #1746, SBC-053000)

[In particular, we strongly support their calls for EPA to:]

• Revise the Health-Based Water Concentration for GenX to 2 ng/L

EPA Response: The EPA disagrees that the HBWC for HFPO-DA should be revised to 2 ng/L. The commenter did not cite underlying data or rationale for the argument/factual assertion it made. Please see additional information in section 4.3.3 of the EPA response in this *Response to Comments* document.

The Chemours Company FC, LLC (Doc. #1845, SBC-046060)

3) EPA's HBWC calculations that are subsequently used in calculating the hazard index for HFPO-DA, PFBS, PFHxS, and PFNA are flawed because of the following critical issues:

a. The reference dose (RfD) value used in the HBWC for HFPO-DA lacks human relevance.

b. The RfD and minimum risk level (MRL) values for PFBS, PFNA, and PFHxS potentially lack human relevance.

c. The body weight-adjusted drinking water intake (DWI-BW) value used in the calculation of the HBWC for HFPO-DA is inappropriate.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

The Chemours Company FC, LLC (Doc. #1845, SBC-046064)

3 EPA's HBWC calculations that are subsequently used in calculating the hazard index (HI) for HFPO-DA, PFBS, PFHxS, and PFNA are flawed.

In setting an MCLG for HFPO-DA, EPA has proposed to use a mixtures approach by combining HFPO-DA with PFBS, PFNA, and PFHxS. As part of this process, EPA derives a health-based water concentration (HBWC) for each constituent that requires a toxicity value such as a reference dose (RfD) or minimal risk level (MRL), a drinking water intake (DWI-BW), and a relative source contribution (RSC). Critical issues with the RfD and DWI-BW values for HFPO-DA result in a HBWC for HFPO-DA that is flawed. These issues are addressed below along with additional commentary on potential issues with the HBWC values for PFBS, PFNA, and PFHxS.

3.1 The RfD value used in the HBWC for HFPO-DA lacks human relevance.

Notwithstanding issues related to the scientific justification for using a mixtures approach for setting a MCLG for HFPO-DA and other PFAS (discussed above), any toxicity value (e.g., RfD or MRL) used in the derivation of drinking water standards (e.g., MCL or MCLG) should have human relevance. In the context of an assumption of dose additivity, it is critical that all the individual chemicals in a mixture of interest have meaningful, human relevant RfD values or else the underlying rationale for summing doses is nullified by the inclusion of some effects that do not occur in humans.

A major driver in the HBWC derivation for HFPO-DA is the RfD. The RfD EPA derived for HFPO-DA is technically flawed as a result of the selection of an inappropriate toxicological endpoint selected as the basis of the RfD, as well as the extrapolation to humans and the application of uncertainty factors. The toxicity endpoint that EPA used to derive its RfD was liver lesions in female mice in a subchronic oral gavage study (EPA 2021). In fact, EPA grouped multiple histopathological lesions in an unusual way that combined adaptive/non-adverse and potentially adverse effects as well as dose-responsive and non-responsive effects into a composite "constellation" of liver effects that were inappropriately subjected to quantitative dose-response modeling. Most toxicity criteria are derived from selecting among multiple candidate RfD (cRfD) values, each comprised of a single effect. As described in Attachment A (Exhibit 2), a National Toxicology Program (NTP) Pathology Working Group (PWG) was convened by EPA to review histological slides from several HFPO-DA studies and concluded that the various liver effects observed represented a "constellation" of effects that were adverse to mice. EPA overinterpreted this statement assuming 1) that these effects are relevant (i.e., adverse) to humans, 2) that early/adaptive responses could/should be combined quantitively with effects that are secondary (i.e., related) to the earlier events, 3) that all the effects are dose-related, and 4) that these combined effects could then be quantitatively modeled. Issues with these assumptions are discussed in detail in Attachment A (Exhibit 2, Section 2-5). In addition, one of the components of the constellation, hepatocellular single cell necrosis, was diagnosed by the NTP-PWG in a manner that appears inconsistent with well-accepted criteria or, at the very least, in a manner inconsistent with classic necrotic characteristics (Attachment A, Exhibit 2, Section 6). More recently, it was demonstrated that some of the hepatocytes putatively considered necrotic by the NTP-PWG, in fact, stain positive for molecular markers of apoptosis thereby calling into questions the NTP-PWG's diagnoses of necrosis (Thompson et al. 2023, see

Attachment B). These findings, in addition to transcriptomic evidence for apoptotic cell death, are consistent with a larger database indicating that HFPO-DA acts through a mode of action (MOA) that occurs in rodents but not in humans (see below).

In addition to the inappropriate grouping and modeling of the constellation of liver effects, several streams of data indicate that these liver responses in mice are consistent with a MOA involving peroxisome proliferator-activated receptor alpha (PPARa) activation that is widely regarded as lacking human relevance. As described in Thompson et al. (2019), HFPO-DA induces liver effects in rodents that are indicative of peroxisomal proliferators, including hepatocellular hypertrophy and hepatomegaly, induction of hepatic peroxisomal b-oxidation activity, as well as transcriptomic responses indicative of PPARa activation (albeit in limited studies ca. 2019). Prior to the release of the EPA final assessment for HFPO-DA (2021), EPA was made aware of unpublished transcriptomic data collected in liver tissues of mice exposed similarly to HFPO-DA as in the studies EPA selected as the basis for its RfD that indicated PPARa activation as the primary response in mouse liver. That work was published prior to the release of EPA's toxicological review but not cited by the EPA (Chappell et al. 2020)—indicating that EPA did not consider all of the available science prior to finalizing its toxicological review. Instead, EPA hypothesized that other MOAs might explain the liver effects in mice. Importantly, subsequent transcriptomic analyses in both primary hepatocytes and in liver samples from the same study that serves as the basis of EPA's RfD, further support PPARa activation as the operative MOA for HFPO-DA in mice and refute alternate MOAs proposed in the liver (Heintz et al. 2022; Klaren et al. 2023, see Attachments C and D). Attachment A (Exhibit 2, Section 2) summarizes much of the information supporting PPARa as the MOA responsible for the liver effects in rodents, which has recently been formalized and published in Toxicological Sciences (Heintz et al. 2023, see Attachment E). Critically, it has long been argued, and widely accepted (Felter et al. 2018), that some effects of PPARa activation in rodents (e.g., liver tumor formation) lack human relevance due to differences in rodent and human downstream signaling pathways (Corton et al. 2018; Klaunig et al. 2003). More recently, Heintz et al. (2023) have demonstrated that earlier non-neoplastic responses to HPO-DA are driven by PPARa activation and thus these effects similarly lack human relevance. As such, liver effects in mice should not be used as the basis of the RfD for HFPO-DA.

It is notable that EPA (2021) acknowledged that a PPARa MOA might have limited human relevance. EPA went on to suggest that the evidence for PPARa activation was inconclusive and hypothesized several alternative MOAs that might, if operative, have human relevance. As discussed in Heintz et al. (2023) and Attachment A (Exhibit 1, Section 3), the evidence for these alternative MOAs is weak at best. Chief among these alternative MOAs was that HFPO-DA induces liver effects through a cytotoxic MOA independent of PPARa activation. However, transcriptomic analyses in liver samples from the same study serving as the basis of EPA's RfD indicate PPARa activation as the most sensitive effect, without significant enrichment of molecular signatures for cytotoxicity with the potential exception of the highest exposure dose, which is likely secondary to PPARa-mediated changes (Heintz et al., 2023; Thompson et al., 2023). In addition, recent transcriptomic analyses of mouse, rat, and human primary hepatocytes

treated with HFPO- DA or positive control chemicals including known agonists of PPARa, PPARg, and known cytotoxic agents, demonstrate concordant transcriptomic responses between HFPO-DA and the PPARa agonist and a lack of concordant transcriptomic responses between HFPO- DA and the other positive control chemicals tested (Klaren et al. 2023, see Attachment D). Overall, histopathological and molecular data published since the release of the EPA (2021) toxicological review strengthen data published prior to the release of EPA (2021) that indicate a PPARa driven MOA in mouse liver that lacks human relevance.

In addition to selection of an endpoint lacking human relevance, EPA also misapplied uncertainty factors in the derivation of the RfD. After conducting interspecies dose adjustments by allometric scaling, EPA applied an unnecessary 3-fold interspecies uncertainty factor (UF_a) for potential pharmacodynamic sensitivities in humans. At the time of EPA's review, there was already data indicating the likely involvement of PPAR a mechanisms that are widely recognized as being more sensitive in rodents than humans. As such, there is no scientific basis to suggest that humans might be more sensitive to the liver effects induced by HFPO-DA in rodents (see Attachment A, Exhibit 3, Section 4.0). EPA also applied an unnecessary 10-fold uncertainty factor for the use of a subchronic study (UF_S) when it applied only a 3-fold UFS to liver effects in the same study in a prior draft review (EPA 2018). As described in detail in Attachment A (Exhibit 3, Section 2), quantitative analyses of liver effects in mice exposed to HFPO-DA for different durations do not provide evidence for a progression of effects warranting a full 10-fold UF_S, which is consistent with what EPA concluded in its 2018 draft review (EPA 2018).

Similar to the UF_S, EPA also applied a 10-fold database uncertainty factor (UF_D) in EPA (2021) but a 3-fold UF_D in its previous review (EPA 2018). This increase in uncertainty is inexplicable given the increase in mechanistic and toxicological studies published on HFPO-DA between 2018 and 2021. As described in detail in Attachment A (Exhibit 3, Section 1), EPA provided a list of reasons purportedly to support the 10-fold UF_D; however, many of the uncertainties could have been addressed by developing an array of candidate RfD (cRfD) values for different toxicities (or organ systems) and selecting the most sensitive effect. Despite the availability of numerous well-conducted studies, EPA only derived cRfD values for liver effects in mice. As shown in Attachment A (Exhibit 3, Sections 1.1-1.3), several additional cRfD values could have been derived but instead EPA "tacked on" additional uncertainty by increasing the UFD from 3 to 10. Attachment A (Exhibit 3, Section 1.4) demonstrates that the UFD applied in other contemporaneous PFAS assessments by EPA had 3-fold UFD values despite having less robust datasets—especially as it applies to reproductive and developmental toxicity studies (see Table 5 of Attachment A, Exhibit 3, Section 1.4). EPA also misinterpreted developmental toxicity data as indicating bioaccumulation of HFPO-DA in embryos, which EPA also stated as a reason for the 10-fold UFD. In fact, the apparent bioaccumulation was likely due to changes in body composition of the embryo/fetus over time that resulted in different levels of HFPO- DA partitioning to the fetus (see Attachment A, Exhibit 3, Section 1.5 for more detail).

Overall, EPA increased the composite UF in the RfD for HFPO-DA 10-fold from 300 to 3000 between 2018 and 2021. It is unusual for the uncertainty in a risk assessment for a chemical to

increase as more mechanistic and toxicological data become available. This increase in uncertainty is not supported. As shown in Table 2 of Attachment A (Exhibit 3, Section 1), the database for HFPO-DA is rather extensive and inconsistent with the use of a 3000-fold composite uncertainty factor that EPA has applied in only ~10% of IRIS risk assessments. EPA (2021) instead compounded various aspects of uncertainty in its RfD derivation for HFPO-DA.

As further evidence that EPA's RfD for HFPO-DA is flawed, the RfD of 3E-6 mg/kg-day is ~500-fold lower than the threshold for toxicological concern (TTC) value of 0.0015 mg/kg-day for Cramer Class III chemicals. Recent studies indicate that PFAS, which have not historically been included in the Munro TTC dataset, can be included among the structurally diverse Class III chemicals with minimal impact on the TTC value (Lea et al. 2022, see Attachment F). It should be noted that the fact that all Cramer Class III compounds have the same TTC value does not imply that they are equipotent or share common MOAs, target organ effects, structural moieties, or are dose additive or otherwise interactive. Importantly, EPA IRIS RfD values for Cramer Class III chemicals tend to be 6-fold higher than the Cramer Class III TTC (Pham et al. 2020). That the RfD for HFPO- DA is so much lower than the TTC implies problems in the RfD derivation, which is consistent with the many issues highlighted above.

EPA Response: The EPA disagrees with the commenter. Please see section 4.3.3 of the EPA response in this *Response to Comments* document. With respect to the commenter's comparison between the RfD for HFPO-DA and the threshold for toxicological concern (TTC) value of 0.0015 mg/kg-day for Cramer Class III chemicals: As noted in section 4.3.3 of this *Response to Comments* document, the final published peer-reviewed human health toxicity assessment that derives the RfD for HFPO-DA is appropriate and sound, reflects the best available peer-reviewed science, and is consistent with agency guidance, guidelines, and best practices for human health risk assessment. The EPA guidance does not allow generalized speculation of how the RfD for HFPO-DA compares to the TTC value of 0.0015 mg/kg-day for Cramer Class III chemicals. Altering an RfD or otherwise deviating from EPA guidance and guidelines in RfD derivation in order to achieve an RfD that is close to the TTC for Cramer Class II chemicals is not in line with EPA guidance.

With regard to the comment questioning why the EPA did not develop chronic RfDs for endpoints other than the liver (e.g., immune and hematological effects), these endpoints were not as consistently observed as the liver effects (see Section 7.1 in USEPA, 2021b). The EPA also did not derive an RfD based on developmental effects (e.g., placental lesions), due to data gaps, specifically, a two-generation reproductive toxicity study (see Section 7.1 in USEPA, 2021b). In addition, the EPA asked external peer reviewers if the agency should consider any other effects or studies for RfD derivation, and they unanimously supported use of the liver endpoint as the RfD.

<u>The Chemours Company FC, LLC (Doc. #1845, SBC-053395)</u>

3.3 The DWI-BW value used in the calculation of the HBWC for HFPO- DA is inappropriate.

In the derivation of a HBWC for HFPO-DA, EPA applied a DWI-BW for lactating women, arguing that this intake relates back to the RfD that was based on parental (F0) female mice exposed to HFPO-DA during premating, gestation, and lactation. EPA argued that DWI- BW for lactating women is highest and therefore should be protective of "women of child baring age, pregnant women, and lactating women". Critically, the RfD developed by EPA is already protective of all human lifestages as a 10-fold human variability factor (UFH) was applied in its derivation. Furthermore, EPA applied a 10-fold UFS for the use of a subchronic study, indicating that EPA did not consider the liver effects in the F0 female mice as a lifestage sensitivity. Had EPA considered the liver effects a lifestage sensitivity, then the endpoint would have been considered a reproductive toxicity endpoint and therefore not require a UFS per EPA guidance (EPA 1991). Nowhere in EPA (2021) are the liver effects in female mice characterized as a reproductive endpoint. In fact, EPA (2021) considered the same liver "constellation" endpoint in males as a candidate RfD but only selected females because it resulted in a slightly lower RfD. As further evidence that EPA did not consider the liver effects a reproductive endpoint, the RfD in the EPA (2018) draft review of HFPO-DA was based on liver effects in male F0 mice because it provided a slightly lower RfD than the same effect in females. As already discussed, it was only after inappropriately combining and modeling several liver effects into a "constellation" that the female liver effects provided a slightly lower RfD than male liver. As such, the appropriate DWI-BW value for the derivation of a HBWC for HFPO-DA (using EPA's flawed RfD) is that of an adult instead of a lactating woman. It is also notable that the SAB review of the PFAS Mixtures Framework specifically stated that use of ingestion rates for lactating women "is not likely to be appropriate" for PFBS or HFPO-DA "since there is no information to indicate that [they] are present in breastmilk" (EPA 2023c).

Using EPA's DWI-BW for lactating women (0.0469 L/kg-day), EPA reports a HBWC of 10 ppt. It is notable that the actual concentration is 12.8 ppt (0.000003 mg/kg-d ¸ 0.0469 L/kg-d ´ 20%). Given the extreme conservativism in EPA's RfD (e.g., endpoint lacking human relevance, application of a maximum 3000-fold composite UF) and use of an inappropriate DWI-BW, the rounding down as opposed to up, in this case reducing the HBWC by ~23% (10 ¸ 13), seems unnecessary. Using the adult DWI-BW (0.034 L/kg-d) results in a HBWC of 17.6 ppt (0.000003 mg/kg-d ¸ 0.034 L/kg-d ´ 20%), rounded to 18 ppt. In summary, notwithstanding the use of an inappropriate RfD for HFPO-DA, EPA has further erroneously calculated a HBWC for HFPO-DA that is almost 2-fold lower than it should be for the RfD EPA selected.

It is notable that EPA used an adult DWI-BW value for the derivation of the HBWC for PFHxS based on follicular cell hyperplasia in male rats. This clearly indicates that EPA does not apply DWI-BW values for lactating women as a matter of policy in their proposed HI approach. As discussed above, the liver effects serving as the basis of the RfD for HFPO-DA were observed in both sexes and the selection of the RfD was driven by numerical considerations as opposed to biological considerations as evidenced by EPA's selection of liver effects in males as the basis of the RfD in EPA (2018) and females in EPA (2021).

EPA Response: The EPA disagrees with this comment. Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

In response to the commenter's statement that the HFPO-DA RfD is already protective of all human lifestages because of the UF_H that was applied: The commenter is conflating two separate elements—the RfD (a measure of toxicity), and the DWI-BW (a measure of exposure). The application of a UF_H to an RfD is to account for uncertainty related to intra-species variability with respect to toxicological response(s). The selection of an appropriate DWI-BW is a separate process during which the EPA considers the sensitive life stage(s) of exposure associated with the critical effect on which the RfD was based in order to apply an appropriate DWI-BW (please see section 4.3.3 of the EPA response in this *Response to Comments* document). As described in the HFPO-DA toxicity assessment (USEPA, 2021b), in the critical study, parental female mice were dosed for two weeks prior to pairing, throughout gestation, and through to lactation day 20 for a total dosing duration of 53 to 65 days. Therefore, exposure corresponded to three potentially sensitive adult female life stages: women of childbearing age, pregnancy, and lactation. The DWI-BW for lactation was appropriately selected because it is the highest (most protective) of the DWI-BWs for these three lifestages (please see section 4.3.3 of the EPA response in this *Response to Comments* document).

In response to the commenter's statement that "EPA applied a 10-fold UF_S for the use of a subchronic study, indicating that EPA did not consider the liver effects in the F0 female mice as a lifestage sensitivity"—the commenter is misunderstanding the purpose of the UF_S. The UF_S is intended to account for potential uncertainty related to using a study with a less-than-chronic exposure duration as the critical study. Its application has nothing to do with whether the critical effect was observed during a potentially sensitive lifestage or not.

In response to the commenter's statement that the SAB review of the PFAS Mixtures Framework specifically stated that use of ingestion rates for lactating women "is not likely to be appropriate" for PFBS or HFPO-DA "since there is no information to indicate that [they] are present in breastmilk"—the commenter is taking this quote out of context. The SAB was commenting on the fact that an example calculation in the draft PFAS Mixtures Framework uses HBWCs for PFOA and PFOS that use DWI-BWs for lactating women. The SAB was simply making the point that a DWI-BW for lactating women may not be appropriate for all PFAS. In fact, the sentence just before the text from the SAB report quoted by the commented reads, "ingestion rates for subgroups other than lactating women (e.g., infants, children, default adults) may be appropriate for HBWCs for other PFAS." At the time of its review and report, the HBWC for HFPO-DA (which uses a DWI-BW for lactating women) did not exist, and therefore, the SAB's general comment about HFPO-DA and the potential that a DWI-BW for lactating women may *not* likely be appropriate, was not made in the context of and/or with the knowledge of the HBWC for HFPO-DA.

In response to the commenter's statement about how the EPA used an adult DWI-BW value for the derivation of the HBWC for PFHxS based on follicular cell hyperplasia in male rats—this DWI-BW was appropriately selected to correspond to the lifestage of the animals that

were exposed and showed effects (i.e., adult male rats). Likewise, the DWI-BW for the critical effect for HFPO-DA was selected based on the lifestage of the animals that were exposed and showed effects (please see section 4.3.3 of the EPA response in this *Response to Comments* document and USEPA, 2024h).

American Chemistry Council (ACC) (Doc. #1841, SBC-044833)

The Reference Dose for HFPO-DA is Based on a Flawed Scientific Approach that has not Been Subject to Appropriate Scientific Review

EPA bases the HBWC for HFPO-DA on liver effects reported in a mouse reproductive/ developmental toxicity screening study, [FN74: E.I. du Pont de Nemours and Company. An oral (gavage) reproduction/developmental toxicity screening study of H-28548 in mice. U.S. EPA OPPTS 870.3550; OECD Test Guideline 421. Conducted by WIL Research Laboratories, LLC, Ashland, OH (2010). DuPont-18405-1037.] despite considerable evidence that the effects in the liver are rodent specific and an absence of supporting data from available epidemiology studies.

Moreover, the Agency chooses to focus on the results of a reproductive/developmental study rather than a 90-day subchronic study that provides additional, relevant hepatic measurements. [FN75: E.I. du Pont de Nemours and Company. H-28548: subchronic toxicity 90-day gavage study in mice. OECD Test Guideline 408. E.I. du Pont de Nemours and Company, Newark, DE. (2010). DuPont-18405-1307.] The EPA analysis also inappropriately combines four liver effects observed in the screening study into a new toxicological endpoint of questionable toxicological relevance. The analysis compounds these problems by applying overly conservative uncertainty factors to derive the HBWC.

The Rodent Liver Effects Underpinning the HFPO-DA Assessment are not Relevant to Humans

EPA's final Toxicity Assessment for HFPO-DA acknowledges that PPARα contributes to the liver effects observed in the laboratory animals and that the PPARα mediated effects "could be more relevant to rodents than humans." The Assessment attempts to provide evidence that other MOAs with potential human relevance could also contribute, including PPAR-gamma, cytotoxicity, and mitochondrial dysfunction, however, and that the liver effects should be considered relevant to humans. [FN76: USEPA. Human Health Toxicity Values for Hexafluoropropylene Oxide (HFPO) Dimer Acid and Its Ammonium Salt (CASRN 13252-13-6 and CASRN 62037-80-3). EPA Document No. 822R-21-010. Office of Water (2021), at 29. (USEPA HFPO-DA Toxicity Assessment)]

Of critical importance in assessing the MOA, the Agency's analysis fails to consider data available from a 2020 peer-reviewed publication by Chappell et al. that provides compelling evidence that the rodent liver effects underpinning EPA's Toxicity Assessment are mediated by PPAR-α and thus are not relevant to humans. [FN77: Chappell GA et al. Assessment of the mode of action underlying the effects of GenX in mouse liver and implications for assessing human health risks. Toxicol Path 48(3):494-508 (2020).] By conducting RNA sequencing of liver

sections from a 90-day subchronic toxicity study, Chappell et al. provide further evidence for activation of PPARα in the mouse livers following HFPO exposure leading to the alteration of cell growth pathways (increased apoptosis and cell proliferation). These two events are consistent with the MOA for PPARα-induced liver tumors which has been determined to be of little relevance to humans (Corton et al. 2018). [FN78: Corton JC et al. The PPARα-dependent rodent liver tumor response is not relevant to humans: addressing misconceptions. Arch Toxicol. 92(1):83119 (2018).] The analysis also provides important information to assess the potential for other MOAs.

Despite the compelling evidence in support of a PPARα MOA, EPA proposes that there may be alternative MOAs (e.g., PPAR-gamma, cytotoxicity, and mitochondrial dysfunction) to suggest effects potentially of greater relevance to humans. EPA analysis of these alternative MOAs lacks scientific rigor and, in some instances, is not supported by the very citations relied upon by the Agency. For example, EPA misinterprets the results of the Li et al. study, which concludes that HFPO-DA has little to no PPAR-gamma binding affinity in either humans or mice and causes minimal changes in PPAR-gamma gene expression. [FN79: Li CH et al. Adipogenic activity of oligomeric hexafluoropropylene oxide (perfluorooctanoic acid alternative) through peroxisome proliferator-activated receptor γ pathway. Environ Science & Tech 53(6):3287-3295 (2019).] EPA similarly misinterprets the findings of the Conley et al. (2019) by confusing PPAR-gamma signaling versus expression and does not consider evidence demonstrating that PPAR-gamma is not highly expressed in the liver. [FN80: Conley JM et al. Adverse maternal, fetal, and postnatal Effects of Hexafluoropropylene oxide dimer acid (GenX) from oral gestational exposure in Sprague-Dawley rats. Environ Health Perspect 127(3):37008 (2019).]

EPA's analysis of the evidence for cytotoxicity or mitochondrial dysfunction as potential MOAs fails to account for all of the available information for the substance. The Agency acknowledges that gaps exist in support for a cytotoxic MOA and that evidence for increased serum liver enzymes that may be clinically relevant is conflicting or contradictory. In addition, EPA's assumption of an increase in focal necrosis is not supported by the available data. Data likewise conflict with EPA's conclusions regarding mitochondrial dysfunction. Multiple studies have demonstrated that PPAR-α, and not mitochondrial dysfunction, mediates the expression of genes involved in mitochondrial beta-oxidation in rodent livers. [FN81: See for example: Cook WS et al. Less extrahepatic induction of fatty acid beta-oxidation enzymes by PPAR alpha. Biochem Biophys Res Commun 278(1):250-7 (2000).]

Available Epidemiological Evidence Does Not Support an Effect of HFPO-DA on Liver Disease in Humans

The evidence for the rodent-specific nature of the liver effects observed in laboratory studies is supported by the available epidemiological data which show no increased risk of liver disease or cancer in populations exposed to HFPO-DA. Notably, the North Carolina Department of Health and Human Services analyzed data from the North Carolina Central Cancer Registry and found no trends of increased cancer risk in the counties with water impacted by HFPO-DA originating from a PFAS manufacturing facility. [FN82: Summary of Selected Cancer Rates for Bladen,

Brunswick, New Hanover and Pender Counties, 1996– 2015, and Comparison to Statewide Rates. https://epi.dph.ncdhhs.gov/oee/pfas/Summary%20of%20Selected%20Cancer%20Rates_all%20counties_7 Nov2018.pdf.] This finding is supported by an analysis of data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program database that shows no increased cancer risk in the counties impacted by HFPO-DA when compared to the United States or the rest of North Carolina. [FN83: Chang ET. Epidemiology of Hexafluoropropylene Oxide Dimer Acid and its Ammonium Salt. Exhibit 5 of Request for Correction of GenX Chemical Toxicity Assessment pursuant to the Information Quality Act filed by Arnold & Porter (March 18, 2022). (Arnold & Porter HFPO-DA RfC)] This analysis also concluded that available epidemiological data "do not support an effect of HFPO-DA on liver disease in humans."

The Assessment's Toxicological Endpoint for HFPO-DA is Unprecedented and Its Use Misapplies Scientific Criteria

The error in the Agency's decision to focus on liver effects is further compounded by combining observations of four separate liver effects - cytoplasmic alteration, single-cell necrosis, focal necrosis, and apoptosis – into a new and unprecedented toxicological endpoint that does not follow evaluation criteria set forth in the peer-reviewed scientific literature. EPA's assessment relies on observations by a pathology work group convened by NTP (NTP PWG) [FN84: USEPA HFPO-DA Toxicity Assessment. Appendix D: NTP PWG Final Report on the Pathology Peer Review of Liver Findings – Final Report (December 4, 2019). (NTP-PWG Report)] to reanalyze pathology cell blocks from a reproductive/developmental study in mice [FN85: E.I. du Pont de Nemours and Company. 2010. An Oral (Gavage) Reproduction/Developmental Toxicity Screening Study of H-28548 in Mice. DuPont-18405-1037. U.S. EPA OPPTS 870.3550; OECD Test Guideline 421 (2010).] using criteria set forth by Elmore et al. [Elmore SA et al. Recommendations from the INHAND apoptosis/necrosis working group. Toxicol Path 44(2):173–88 (2016).] As summarized below, however, the NTP PWG misapplies the Elmore criteria and does not consider the information in the context of available information on the MOA. [FN87: Notably, the NTP-PWG concludes that the liver lesions observed are "indicators of adversity within the confines of this study," where "[a]dversity is a term indicating 'harm' to the test animal within the constraints of a given study design." (NTP-PWG Report, at D-22). The Work Group offered no conclusions as to the relevance of the findings to human risk assessment.]

The NTP PWG's observations do not properly distinguish two possible observed effects - single-cell necrosis, on the one hand, and apoptosis, on the other. As indicated above, the PPAR-α MOA, which is not relevant to humans, results in apoptosis. Pursuant to the criteria described by Elmore et al., necrotic cells have a pale cytoplasm, whereas apoptotic cells are hypereosinophilic. [FN88: Containing a high number of a certain type of white blood cells.] However, contrary to these criteria, the NTP PWG characterizes hypereosinophilic cells as necrotic, not as apoptotic. Further, while the Elmore criteria recognize that not all apoptotic cells

are small or rounded, the NTP PWG only characterizes small or rounded cells as apoptotic. Elmore et al. also note the importance of using biochemical markers to distinguish necrosis from apoptosis. Biochemical markers—including the caspase-3 immunostaining reported by Chappell et al. — confirm apoptosis following HFPO-DA exposure.

Additionally, there are important discrepancies in the NTP PWG's observations of focal necrosis (i.e., necrosis involving larger groups of functional cells within the liver). The focal necrosis observed by the NTP PWG lacked a dose-response relationship — focal necrosis was present in some control animals, there was no statistically significant increase in test animals, and a 10-fold increase in HFPO-DA dose resulted in minimal or no increase in focal necrosis. Moreover, it is well established that focal necrosis may be caused by biological processes other than direct chemical exposure and is not necessarily a progression from single-cell necrosis. [FN89: Hall AP et al. Liver hypertrophy: a review of adaptive (adverse and non-adverse) changes – conclusions from the 3rd international ESTP expert workshop. Toxicologic Pathol 40:971-994 (2012).]

EPA then combines the four liver effects observed by the NTP PWG into a never-before- used toxicological endpoint — a so-called "constellation of liver effects." Previously, EPA relied on single-cell necrosis as the toxicological endpoint but inexplicably pivoted to this new endpoint in its final Toxicity Assessment. Not only is EPA's "constellation of liver effects" unprecedented and a significant deviation from its standard toxicity assessment methods, but it is also at odds with the science. As described above, EPA misapplies the criteria from Hall et al. in determining whether liver effects observed by the NTP PWG are adverse effects. [FN 90: Ibid.] Had EPA properly applied these scientific criteria, the Agency would have instead correctly determined that dosing levels in treated mice did not generate effects relevant to humans.

EPA's HFPO-DA Analysis Inappropriately Rejects Results from a 90-Day Study

EPA bases its HBWC for HFPO-DA on liver effects reported in a mouse reproductive/ developmental toxicity screening study, [FN91: E.I. du Pont de Nemours and Company. An oral (gavage) reproduction/developmental toxicity screening study of H-28548 in mice. U.S. EPA OPPTS 870.3550; OECD Test Guideline 421. Conducted by WIL Research Laboratories, LLC, Ashland, OH (2010). (DuPont-18405-1037)] despite the fact that a 90-day subchronic study is available that provides additional, relevant hepatic measurements. [FN92: E.I. du Pont de Nemours and Company. H-28548: subchronic toxicity 90-day gavage study in mice. OECD Test Guideline 408. E.I. du Pont de Nemours and Company, Newark, DE (2010). (DuPont-18405-1307)] Hall et al. note the importance of considering available information on histological and clinical pathological changes when evaluating the relevance of rodent liver effects to humans. Both the reproductive/development and 90-day studies provide information on liver cell necrosis, but the 90-day study also includes information on key clinical chemistry – including alanine aminotransferase (ALT), alkaline phosphatase (ALP) and aspartate aminotransferase (AST). The elevation of these enzyme levels provides important clinical correlations to the observed changes in pathology. In its assessment, EPA dismisses the results from the 90-day study because of the smaller sample size [FN93: 10 animals/exposure group versus 24/group in the

reproductive/developmental study.] without addressing the other significant aspects of the two studies.

The consistency of the necrosis data with the liver enzyme results available from the 90-day study, provides a more complete picture of what is happening in the liver than the more limited data available from the reproductive/developmental study used in the assessment. EPA's concern about the statistical power of the 90-day study is further eroded by the fact that the authors did not observe necrosis in any of the animals exposed to levels of 0.5 mg/kg-day or less. The minimal necrosis reported at these levels in the reproductive/ developmental study may suggest an adaptive, non-adverse reaction in the mice or a response to other stressors for which no acknowledgement has been made.

The decision to reject the liver results from the 90-day study also raises concerns about the approach the Agency has taken in integrating data from the various studies as part of its systematic review. Both of the studies in question were assigned an overall quality level of "High" in the Agency's data evaluation tables. [FN94: USEPA HFPO-DA Toxicity Assessment, at 32.] In particular, both studies received the best possible weighted score of "1" in relation to the number of animals per group. [FN95: USEPA. Human Health Toxicity Values for Hexafluoropropylene Oxide (HFPO) Dimer Acid and Its Ammonium Salt (CASRN 13252-13-6 and CASRN 62037-80-3). Public Comment Draft. EPA-823-P-18-001. Office of Water (2018). Appendix B. (USEPA Draft HFPO-DA Toxicity Assessment)] Any concern about the number of animals in the 90-day study should have been reflected in the data evaluation and scoring, not as part of an arbitrary decision to choose one study over another based solely on generating a lower value.

Based on the liver effects reported in the 90-day study, the lowest observed adverse effect level (LOAEL) for single cell necrosis is 5.0 mg/kg-day and the no observed adverse effect level (NOAEL) is 0.5 mg/kg-day. [FN96: Arnold & Porter HFPO-DA RfC. Exhibit 3 - Issues with the Uncertainty Factors in USEPA Toxicity Assessment (2021). Prepared by ToxStrategies, at 15. ToxStrategies indicates that no Benchmark Dose Model fits the data.] Although EPA did not conduct benchmark dose modeling (BMD) for the data available from the 90-day study on the four effects included in its constellation of liver effects, the lower bound of the BMD at 10 percent risk is calculated to be 0.2 – well above the value derived by EPA from the reproductive-developmental study. [FN97: Ibid, at 16.]

The HFPO-DA Assessment Uses Inappropriate and Significantly Inflated Uncertainty Factors

EPA's use of a 3000-fold total uncertainty factor for HFPO-DA is inconsistent with the significant amount of toxicity data available for HFPO-DA and the Agency's approach to uncertainty for other chemicals. This includes a tenfold increase in total uncertainty factors between EPA's 2018 draft assessment [FN98: USEPA Draft HFPO-DA Toxicity Assessment.] and the final Toxicity Assessment attributed to increases in the database uncertainty factor (UFD) and the subchronic-to-chronic uncertainty factor (UFS), each from 3 to 10. Ten is the maximum possible value EPA could have selected for each of these uncertainty factors. EPA's selections of

10 for these uncertainty factors is not supported by the science. Additionally, the available information does not support EPA's selection of an interspecies uncertainty factor here.

In the final Toxicity Assessment, EPA claims that new data and studies have made the database of toxicity studies for HFPO-DA more uncertain with respect to potential reproductive or developmental effects. That additional data and studies could result in more uncertainty is plainly counterintuitive, and EPA has not reasonably explained how this could be the case here. Moreover, the new studies relied upon by EPA actually reduce, rather than increase uncertainty. The observed effects in these newly considered studies do not occur until levels of exposure that are significantly higher than the point of departure identified by EPA. It is not scientifically defensible to justify increasing the UFD based on these newer studies.

EPA also indicates that the UFD is based on limited testing of developmental toxicity and immunological responses. Although data from a 2-generation reproductive toxicity and additional immunotoxicity studies would be valuable, the available evidence suggests that any developmental and immune effects are likely to occur at exposure levels that are comparable to the liver effects that are the basis of the toxicity value. Two studies investigating developmental and reproductive effects are available – the mouse study previously discussed (Dupont-18405-1037) and a prenatal developmental toxicity study in rats. [FN99: E.I. du Pont de Nemours and Company. An Oral (Gavage) Prenatal Developmental Toxicity Study of H-28548 in Rats. U.S. EPA OPPTS 850.3700; OECD Test Guideline 414. Conducted by WIL Research Laboratories, LLC Ashland, OH (2010). DuPont-18405-841] While these studies have reported developmental effects, the LOAELs and NOAELs for the most sensitive effect (pup body weight in mice) are consistent with the liver results. Similarly, a study of immunological effects which suggests T cell-dependent antibody response (TDAR) suppression in mice treated with 100 mg/kg-day [FN100: Rushing B et al. Evaluation of the immunomodulatory effects of 2,3,3,3-tetrafluoro-2(heptafluoropropoxy)- propanoate in C57BL/6 mice. Toxicol Sci 156(1):179– 189 (2017).] – well above the NOAEL/LOAEL reported in the liver studies. Other studies reported decreases in spleen weight after 28 days, but again only when treated with 100 mg/kg-day. Based on these data, it is reasonable to conclude that toxicity value generated from the liver effects observed in the 90-day study will provide sufficient protection against potential developmental and immunotoxic effects and obviates the need to assign an additional uncertainty factor.

Further, EPA reasons that since its chronic toxicity value relies on effects in female mice in a reproductive/developmental study application of an uncertainty factor of 10 is appropriate for scaling from subchronic to chronic exposure (UFS). However, there is no strong indication of a progression of rodent liver lesions with longer exposure duration. Moreover, EPA guidelines indicate that there no UFS should be applied since the critical effects in female mice are from a maternal rodent toxicity study for which "an uncertainty factor is not [to be] applied to account for duration of exposure." [FN101: USEPA. Guidelines for Developmental Toxicity Risk Assessment. EPA/600/FR-91/001. Risk Assessment Forum (1991), at 42. (USEPA Development Toxicity Guidelines)]

EPA Did Not Seek Additional Public Comment Despite Making Significant Changes to its Draft Assessment for HFPO-DA

In light of the dramatic change in both methodology and results from Agency's draft assessment in 2018 and its final Toxicity Assessment for HFPO-DA in 2021, EPA should have provided additional opportunity for public comment before publishing the final version of the assessment. The failure to provide an opportunity for stakeholder input on these changes runs counter to the appropriate notice and comment process.

EPA Response: The EPA disagrees. Please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Also, the commenter repeats concerns that they expressed and the EPA addressed during the public comment period for the draft HFPO-DA toxicity assessment. As stated in USEPA (2021b):

"The reproductive developmental study (DuPont-18405-1037, 2010) has greater statistical power than that of the 90-day subchronic study (DuPont-18405-1307, 2010) because of its greater sample size/group. In the reproductive/developmental study, DuPont evaluated 22–25 mice/dose group while the 90-day study in mice used 10 mice/dose group for liver endpoints. Additionally, one female mouse per HFPO dimer acid ammonium salt dose group died before study completion, bringing the sample size to nine mice/dose group in the 90-day toxicity study in mice (DuPont-18405-1307, 2010). The difference in the number of mice per dosing group between the 90-day study and the reproductive/developmental study might have an impact on statistical power (i.e., ability to observe liver effect levels in these studies). For example, in the 90-day study, adverse effects in the liver were observed in the high-dose 5 mg/kg/day group, yet there are indications of liver damage in the 0.5 mg/kg/day group. Specifically, absolute and relative liver weight increased relative to control mice in males by 12% and 11%, respectively, at 0.5 mg/kg/day. In males dosed with 0.5 mg/kg/day, 4/10 (40%) livers were observed to be discolored, compared to 0/10 (0%) for control mice. There were also increases in serum liver proteins at 0.5 mg/kg/day in males, although they did not differ significantly from control. AST, ALP, and ALT increased 35%, 40%, and 35%, respectively, compared to control (DuPont-18405-1307, 2010). Finally, histopathological liver effects were observed at 0.5 mg/kg/day in both sexes. Specifically, the NTP Pathology Working Group (PWG; see section 4.3 or appendix D of EPA, 2021a) noted that 10/10 (100%) male mice at the 0.5 mg/kg/day dose exhibited cytoplasmic alteration, compared to 0/10 (0%) in control. ACC also claimed that the longer exposure time in the 90-day study should have improved chances to observe necrosis despite the lower statistical power. However, this was not the case as evidenced by the NOAEL (0.1 mg/kg/day) from the reproductive/developmental study, which was lower than the NOAEL from the 90-day study (0.5 mg/kg/day) (see Table 12 in the assessment). The fact that liver enzyme data were not collected in the reproductive/developmental study does not negate the liver findings of cell death that were observed and recorded by the NTP PWG (appendix D in EPA, 2021a) as part of the adverse constellation of liver lesions. Although NTP classified cytoplasmic

alteration as part of the constellation of liver lesions that are considered adverse, no other liver lesions (i.e., single-cell or focal necrosis or apoptosis) were observed at the 0.5 mg/kg/day dose level in males. Consistent with the Hall criteria (Hall et al., 2012), EPA did not consider the cytoplasmic alteration alone as an adverse effect in this dose group. Additionally, 2/9 (22%) of the female mice in the 0.5 mg/kg/day dose group exhibited focal necrosis. Because 1/10 (10%) female mice in the control group also exhibited focal necrosis, a dose response was not observed for the constellation of liver lesions in the female mice in this study. Because of the significant uncertainties in the results of the 90-day study, EPA determined that the reproductive/developmental study was not only more sensitive for liver effects but also more completely represents the constellation of hepatic effects than the chronic."

Furthermore, the EPA sought external peer review of its selection and use of the reproductive developmental study (DuPont-18405-1037, 2010) as the critical study at two different times in the toxicity assessment development process. Specifically, the first letter peer review asked peer reviewers if "the selection of the critical study and critical effect for the derivation of the subchronic and chronic RfDs for GenX chemicals [was] scientifically justified and defensible" and to "provide rationale and detail an alternative critical study" if they did not agree with the use of DuPont 18405-1037, 2010 as the critical study (USEPA, 2018b). The five peer reviewers unanimously agreed with the selection of DuPont 18405-1037 (2010) as the critical study and none of the peer reviewers identified any study deficiencies. Similarly, the second external peer review asked the seven peer reviewers if "the selection of the oral reproductive/developmental toxicity study in mice (DuPont-18405-1037, 2010) for the derivation of the subchronic and chronic RfDs for GenX chemicals [is] scientifically justified and clearly described?" (USEPA, 2021i). Again, all seven peer reviewers found the use of DuPont-18405-1037 (2010) scientifically justified. Both peer-review panels unanimously approved the EPA's selection of the critical study for RfD derivation (USEPA, 2018b and USEPA, 2021i).

In response to the commenter's claim that the EPA's analysis of alternative MOAs is not supported and that the EPA misinterpreted the findings of Li et al. (2019) and Conley et al. (2019), the EPA disagrees. The Li et al. (2019) study reported data demonstrating that HFPO-DA does bind both mouse and human PPAR gamma, albeit with lower affinity than either PFOA or HFPO-TA (trimer acid). Further, Li et al. (2019) also reported statistically significant upregulation of PPAR gamma target genes and lipid accumulation from HFPO-DA exposure in human preadipocyte cells, again with similar or lower in vitro potency than PFOA and HFPO-TA. Subsequent publications from EPA, including Houck et al. (2021) and Evans et al. (2022), reported in vitro PPAR gamma activation by HFPO-DA. Further, Conley et al. (2019) reported quantitative expression of genes in maternal and fetal livers using a targeted PPAR signaling array with statistically significant upregulation of multiple PPAR gamma target genes including Lpl, Pck1, Aqp7, Scd1, Hsp1, Gk, and Txnip, among others that are putative targets of PPAR gamma. It is well documented in the literature that PPAR gamma is expressed in the liver, but to a lesser overall degree of expression than in adipose tissue. Overall, the available data indicate that HFPO-DA is able to activate the PPAR gamma receptor, which is present in the liver and other tissues, and potentially affect biological processes associated with that receptor.

HFPO-DA. EPA's (2021b) selection of an RfD of 0.000003 mg/kg/day for HFPO-DA is likewise nconsistent with sound scientific process and guidance. Not only is the study it selected unpublished (DuPont 2010a), but EPA also selected a critical effect of "constellation of liver lesions." The study, which was a reproductive and developmental study in mice, indicated that the various hepatic effects were not consistently observed in male and female mice. However, EPA inappropriately combined these effects in order to consider it as a single critical effect, in violation of its own guidance. The resultant no-observed-adverse-effect level (NOAEL) and lowest-observed-adverse-effect level (LOAEL) values are 0.1 mg/kg-day and 0.5 mg/kg-day, respectively. EPA's IRIS Handbook states that common endpoints are "the same specific outcome measurement, not just any endpoint in a common target organ" indicating that to be combined, the observed effects have to be the same.

Combining the observed liver effects is inappropriate because some of the liver effects considered in the "critical effect" were not clearly adverse; the effects were either adaptive changes or unclear in their adversity (e.g., hepatocellular hypertrophy, enlargement of liver cells, changes in cytoplasm of liver cells) (USEPA 2021b). These effects could occur through different modes of action or were not actually adverse effects (Hall et al. 2012), which makes combining them inappropriate per EPA's IRIS Handbook. Because differences between exposed and unexposed animals were only observed when all observed liver effects were combined, EPA could not have established a NOAEL and LOAEL based on any individual effect.

EPA also violated proper systematic review processes when it inexplicably disregarded other studies that did not find such a "constellation" of hepatic effects in rodents exposed to HFPO-DA. For instance, DuPont (2010b) reported a NOAEL of 0.5 mg/kg-day in a separate unpublished mouse study, rather than a NOAEL of 0.1 mg/kg-day applied by EPA. DuPont (2010b) was unable to establish a dose-response in female mice in this study (USEPA 2021b). Similarly, hepatic effects were not observed at such low doses in a DuPont chronic rat study (DuPont 2013). These scientifically flawed practices result in a critically flawed RfD value. EPA (2021b) itself demonstrates its uncertainty in the overall evidence base with its RfD by applying an uncertainty factor of 3,000. In other words, the significant uncertainty inherent in EPA's RfD highlights its unsuitability as the basis of a regulatory value. As noted for PFHxS, an uncertainty factor of 3,000 is the maximum that could be considered as the basis of reference value according to EPA's IRIS Handbook and USEPA (2002).

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document. Commenter incorrectly asserts that the final RfD for HFPO-DA in the EPA's 2021 final toxicity assessment for HFPO-DA (US EPA, 2021b) is "inconsistent with sound scientific process and guidance," in part, because the critical study used for RfD derivation is unpublished. The EPA disagrees. First, the study was submitted to the EPA Office of Pollution Prevention and Toxics under the Toxic Substances Control Act (TSCA) (Title 15 of the U.S.C. § 2601 et seq.) pursuant to a consent order concluding new chemical review of HFPO-DA. The

consent order specifies that the submitted studies must follow the Organization for Economic Cooperation and Development (OECD) Test Guideline (TG) 407 (OECD, 2008) and meet Good Laboratory Practices (GLP) standards. The study satisfied these requirements and was accepted by the EPA under the consent order.

The study subsequently underwent a quality evaluation (internal peer review) by the EPA Office of Water as part of its development of the HFPO-DA toxicity assessment. The process of selecting Dupont 18405-1037 (2010) as EPA's critical study for its HFPO-DA toxicity assessment involved a rigorous study review and quality evaluation of all dose-response studies according to the systematic review procedures outlined in the EPA's final *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a). The EPA selected Dupont 18405-1037 (2010) as the critical study based on an adverse outcome at the lowest tested dose from a sufficient quality study (based on study quality evaluation as part of systematic review). Also, the study report was made publicly available by the agency as part of development of the HFPO-DA toxicity assessment.

Then, the EPA sought external peer review of the agency's draft HFPO-DA toxicity assessment, including its selection and use of the critical study, at two different times in the toxicity assessment development process. Specifically, the first letter peer review asked peer reviewers if "the selection of the critical study and critical effect for the derivation of the subchronic and chronic RfDs for GenX chemicals [was] scientifically justified and defensible" and to "provide rationale and detail an alternative critical study" if they did not agree with the use of DuPont 18405-1037 (2010) as the critical study (USEPA, 2018b). The five (5) peer reviewers unanimously agreed with the selection of DuPont 18405-1037 (2010) as the critical study and none of the peer reviewers identified any study deficiencies. Similarly, a second external peer review asked seven (7) peer reviewers if "the selection of the oral reproductive/developmental toxicity study in mice (DuPont-18405-1037, 2010) for the derivation of the subchronic and chronic RfDs for GenX chemicals [is] scientifically justified and clearly described?" (USEPA, 2021i). Again, all seven peer reviewers found the use of DuPont-18405-1037 (2010) scientifically justified. Both peer-review panels unanimously approved the EPA's selection of the critical study for RfD derivation (USEPA, 2018b and USEPA, 2021i).

To summarize, the study was conducted following established international guidelines and GLPs, was accepted by the EPA under TSCA, underwent a quality evaluation (internal peer review) by human health scientists in the EPA Office of Water, and was externally peer reviewed twice as the critical study in the HFPO-DA toxicity assessment (and made publicly available as part of assessment development). These review processes and standards are consistent with the EPA using the "best available, peer-reviewed science and supporting studies conducted in accordance with sound and objective scientific practices; and data collected by accepted methods or best available methods (if the reliability of the method and the nature of the decision justifies use of the data)" per SDWA. For the above-described reasons, it was appropriate for the EPA to consider DuPont-18405-1037 (2010) as the critical study.

The agency has a long history of using study reports produced by contractors or industry as critical studies in EPA human health risk assessments for pesticides under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and industrial chemicals under TSCA. These types of studies submitted by industry may be important for new and emerging chemicals for which there may not be a robust database of studies publicly available in peer reviewed journals. Additionally, the EPA notes that other recent toxicity assessments for PFAS (e.g., USEPA, 2023m; USEPA, 2023n) also rely on industry-conducted studies as the critical studies. The practice is also recognized by and consistent with the ORD Staff Handbook for Developing IRIS Assessments (Table 2-5) which indicates that strategies for literature identification can include the identification of "Unpublished studies, information submitted to EPA under TSCA Section 4 (chemical testing results); Section 8(d) (health and safety studies); Section 8(e) (substantial risk of injury to health or the environment notices)." For purposes of development of drinking water standards, any supporting information or studies would need to meet the requirements of Section 1412(b).

Regarding the commenter's claim that the EPA inappropriately combined the liver effects observed in the critical study in order to consider it as a single critical effect, in violation of its own guidance—the EPA disagrees. The text from the *ORD Staff Handbook for Developing IRIS Assessments* (USEPA, 2022a) quoted by the commenter is from a section of the Handbook that describes possible considerations a risk assessor might consider when judging whether to perform dose-response modeling of data combined from multiple different studies. This quoted text from the Handbook is taken out of context and is not applicable to the critical study and effect selection for HFPO-DA, which did not combine data from multiple different studies, nor does the quoted text represent a requirement of the process outlined in the Handbook that must be followed. Also, as described above, two external peer review panels agreed with the use of the constellation of liver lesions as the critical effect.

<u>The Chemours Company FC, LLC (Doc. #1845, SBC-046053)</u>

II. EPA's proposed regulation of HFPO-DA is also arbitrary and capricious because it is based on substantial scientific flaws

As discussed above, EPA is proposing to regulate HFPO-DA as part of a Hazard Index for mixtures of multiple PFAS compounds, using a HBWC level of 10 ppt for HFPO- DA. To derive this 10 ppt level for HFPO-DA, EPA started with its 2021 Human Health Toxicity Assessment for GenX Chemicals ("HFPO-DA toxicity assessment") and the chronic reference dose it calculated therein, based on a "constellation" of liver effects observed in mice exposed to HFPO-DA multiplied by 3,000 times uncertainty factors. PFAS National Primary Drinking Water Regulation Rulemaking, 88 Fed. Reg. 18638, 18646 (proposed Mar. 29, 2023). On top of that extremely conservative reference dose, EPA then applied a 20% relative source contribution ("RSC") factor based on the default assumption, not supported by the actual data, that 20% of HFPO-DA exposure occurs through drinking water and the remaining 80% occurs through other sources. Id. The resulting 10 ppt level for HFPO-DA is the same as EPA's 2022 drinking water

health advisory level for HFPO-DA. Id. Then, for this Proposed Rulemaking, EPA effectively ratcheted the level down even further by including it as part of a Hazard Index for mixtures of multiple PFAS compounds, such that lower levels of HFPO-DA could contribute to exceedances of the Hazard Index if other compounds in the Hazard Index are also detected. In fact, depending on the levels at which the other PFAS compounds are detected, the MCL for HFPO-DA could effectively be zero.

Chemours has previously made several submissions to EPA regarding the scientific flaws in EPA's HFPO-DA toxicity assessment, RSC, and health advisory, including:

• January 13, 2022 presentation slides from Chemours meeting with EPA Office of Water

• January 28, 2022 email from Sheryl Telford, Chemours, to Zach Schafer and Matthew Klasen, EPA, with attached meeting presentation

• March 18, 2022 Request for Correction Letter and Exhibits

• April 29, 2022 email from Sheryl Telford, Chemours, to Betsy Behl, EPA, with attached meeting presentation

• April 29, 2022 follow-up email from Sheryl Telford, Chemours, to Betsy Behl, EPA

• May 25, 2022 email from Sheryl Telford, Chemours, to Betsy Behl, EPA

• May 27, 2022 Request for Correction Supplement

• May 31, 2022 letter from Sheryl Telford, Chemours, to Betsy Behl, EPA, and attached studies

• February 7, 2023 email from Sheryl Telford, Chemours, to Betsy Behl, EPA, with attached studies

Chemours hereby incorporates these prior submissions into these comments and requests that they be added to the administrative record for this rulemaking.

Additionally, Chemours has filed a petition for review of EPA's HFPO-DA health advisory in the United States Court of Appeals for the Third Circuit, and that proceeding remains pending. Chemours v. U.S. EPA, Case No. 22-2287. Chemours incorporates into these comments its briefings filed in the Third Circuit proceeding, and requests that those briefings and the administrative record for that proceeding be added to the administrative record for this rulemaking. Chemours also requests that EPA's responses to Chemours' Freedom of Information Act ("FOIA") request for records concerning EPA's HFPO-DA toxicity assessment be added to the administrative record for this rulemaking.[FN16: FOIA Request No. EPA-2022-000577, available at https://foiaonline.gov/foiaonline/action/public/submissionDetails?trackingNumber=EPA-2022-000577&type=request.]

The subsections that follow provide a brief summary of the scientific flaws at every step of EPA's development of its proposed regulation of HFPO-DA—from its HFPO-DA toxicity

assessment and reference dose, to its default exposure assumptions and relative source contribution, to its aggregation of HFPO-DA with multiple other compounds in a Hazard Index. Further details are provided in the materials listed above and incorporated herein by reference, and in the supporting technical comments prepared by Dr. Chad Thompson and Dr. Melissa Heintz, attached hereto as Exhibit 1.

A. EPA's toxicity assessment and corresponding reference dose for HFPO-DA are scientifically flawed

EPA's HFPO-DA toxicity assessment, and the reference dose calculated therein, contains significant deviations from standard EPA toxicity assessment methods and is not supported by the weight of scientific evidence. For example, and as set forth in detail in Chemours' March 18, 2022 Request for Correction Letter and Exhibits and in the attached technical comments of Dr. Chad Thompson and Dr. Melissa Heintz:

• The rodent liver effects underpinning the assessment are peroxisome proliferator- activated receptor alpha ("PPAR-alpha") effects that are not relevant to humans.

• The assessment did not evaluate—or even acknowledge—a critically important 2020 peer-reviewed published study by Dr. Grace A. Chappell et al. that provides compelling additional evidence that the rodent liver effects underpinning the assessment are not relevant to humans.[FN17: See Chappell, G.A., C.M. Thompson, J.C. Wolf, J.M. Cullen, J.E. Klaunig, and L.C. Haws. 2020. Assessment of the Mode of Action Underlying the Effects of GenX in Mouse Liver and Implications for Assessing Human Health Risks. Toxicologic Pathology 48(3):494-508.]

• References in the assessment to non-PPAR-alpha modes of action are not supported by scientific data and are, in some cases, directly contradicted by the very sources relied upon by EPA.

• The assessment relies on observations by the National Toxicology Program Pathology Working Group ("NTP PWG") that do not follow evaluation criteria set forth in the peer-reviewed scientific literature.

• The assessment's new toxicological endpoint—a "constellation of liver effects"— is unprecedented, and misapplies scientific criteria in determining whether observed effects are in fact adverse effects in the context of a human health risk assessment.

• EPA did not take into account available epidemiological evidence showing no increased risk of cancers or liver disease attributable to exposure to HFPO-DA.

Further, EPA's HFPO-DA toxicity assessment uses inappropriate and significantly inflated uncertainty factors that are inconsistent with EPA's own guidance and practice in other toxicity assessments. In fact, one of EPA's external peer reviewers described EPA's uncertainty factors in the HFPO-DA toxicity assessment as "extreme" and "excessive."[FN18: U.S. EPA, EPA Doc. No. 822R-21-009, Response to Additional Focused External Peer Review of Draft Human Health

Toxicity Values for Hexafluoropropylene Oxide (HFPO) Dimer Acid and Its Ammonium Salt (GenX Chemicals) at 18 (Oct. 2021), https://www.epa.gov/system/files/documents/2021-10/epa_2nd- response-to-peer-review_genx_508.pdf (comments of David Alan Warren, MPH, Ph.D., Program Dir., Env't Health Sci., Univ. of S.C. Beaufort).]

Additional scientific research sponsored by Chemours and conducted since EPA's 2021 HFPO-DA toxicity assessment further underscores the assessment's scientific flaws. This research has already resulted in three studies, all approved for publication by independent, peer-reviewed journals, that provide further compelling and direct evidence that the rodent liver effects from HFPO-DA are mediated through the PPAR-alpha mode of action that is not relevant to humans.[FN19: Melissa M. Heintz et al., Evaluation of Transcriptomic Responses in Livers of Mice Exposed to the Short- Chain PFAS Compound HFPO-DA, 4 Front. Toxic. 1 (2022); Melissa M. Heintz et al., Assessment of the Mode of Action Underlying Development of Liver Lesions in Mice Following Oral Exposure to HFPO-DA and Relevance to Humans, 192 Toxic. Scis. 15 (2023); Chad M. Thompson et al., Assessment of Mouse Liver Histopathology Following Exposure to HFPO-DA with Emphasis on Understanding Mechanisms of Hepatocellular Death, Toxic. Pathology (Mar. 2023).] Additionally, the in vitro human and rodent hepatocyte study that Chemours is sponsoring is in the analysis phase, and publication of the results is expected to be forthcoming. The data collected from that study also show that the rodent liver effects from HFPO-DA are mediated through the PPAR-alpha mode of action and not the alternative modes of action hypothesized by EPA in its HFPO-DA toxicity assessment. The findings from this study provide additional compelling evidence that the rodent liver effects should not be used as the basis for the toxicity value for HFPO- DA, which underpins EPA's proposed regulation here.

B. EPA's default exposure assumptions and corresponding relative source contribution for HFPO-DA are scientifically flawed

On top of its flawed HFPO-DA toxicity assessment and corresponding reference dose, discussed above, EPA then applied a 20% relative source contribution ("RSC") factor (i.e., an additional fivefold downward adjustment) based on the default assumption, not supported by the actual data, that 20% of HFPO-DA exposure occurs through drinking water and the remaining 80% occurs through other sources.[FN20: This default assumption is not only unsupported by science, but also exceeded EPA's statutory authority under the SDWA, which is expressly limited to regulating contaminants "in water." 42 U.S.C. [sec] 300f(6). This constraint leaves no room for EPA to set levels based on other exposures covered by other regulatory regimes—much less to ground a MCL primarily (80%) on assumed non-drinking-water exposures.] As purported justification for selecting a 20% RSC for HFPO-DA, EPA cited to guidance it had issued under the Clean Water Act, which cabins the range of RSC values from a maximum of 80% to a minimum of 20%.[FN21: U.S. EPA, EPA Doc. No. 822-B-00-004, Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (2000), https://nepis.epa.gov/Exe/ZyPURL.cgi?Dockey=20003D2R.txt.] But that guidance permits use of the 20% minimum as a "default" assumption only "when adequate exposure data do not

exist," and strongly cautions against using the minimum default when "available" information "more accurately reflects exposures than automatically using a default value."[FN22: Id.]

There is no indication that EPA has assessed the available data on potential sources of public exposure to HFPO-DA. But Chemours previously provided EPA with 22 independent reports containing exposure data from the United States, Europe, and China, which uniformly showed that the "only relevant exposure pathway for HFPO-DA is drinking water" and there are no significant levels of exposure from other sources such as food, dust, air, soil, consumer products, and firefighting foam.[FN23: Letter and Attachments from Sheryl Telford, Chemours, to Elizabeth (Betsy) Behl, U.S. EPA (May 31, 2022).] EPA has also had in its possession federally generated data, collected by the Agency for Toxic Substances and Disease Registry, which had monitored several separate "Exposure Assessment" sites and found that HFPO-DA "was not detected in any urine or dust samples" at any of the sites.[FN24: EPA Doc. No. ED_006421_00013324-00001, FOIA Request No. EPA-2022-000577, available at https://foiaonline.gov/foiaonline/action/public/submissionDetails?trackingNumber=EPA-2022-000577&type=request.] EPA has not, and cannot, explain why, despite all this data, it is appropriate to continue using the 20% default assumption for a nationwide regulation.

EPA's use of the 20% default assumption appears to reflect its underlying and incorrect view that public exposure to HFPO-DA will mirror that of PFOA, which was used far more extensively than HFPO-DA. For example, internal correspondence involving the Director of EPA's Health and Ecological Criteria Division stated (incorrectly) that HFPO-DA "may be used in the manufacture of the same or similar commercial fluoropolymer end products which formerly used PFOA."[FN25: EPA Doc. No. ED_006421_00011953-00001, FOIA Request No. EPA-2022-000577, available at https://foiaonline.gov/foiaonline/action/public/submissionDetails?trackingNumber=EPA-2022-000577&type=request] And in its HFPO-DA health advisory, EPA stated (again incorrectly) that "[s]ince GenX chemicals are substitutes for PFOA, products (e.g., some nonstick coatings, aqueous film-forming foam [AFFF]) that were previously made using PFOA may now rely on GenX chemicals."[FN26: U.S. EPA, Drinking Water Health Advisory: Hexafluoropropylene Oxide (HFPO) Dimer Acid (CASRN 13252-13-6) and HFPO Dimer Acid Ammonium Salt (CASRN 62037-80-3), Also Known as "GenX Chemicals" (2022), https://www.epa.gov/system/files/documents/2022-06/drinking-water-genx-2022.pdf.]

Chemours has previously explained to EPA multiple times that this assumption about HFPO-DA is incorrect.[FN27: See, e.g., Email from Sheryl Telford, Chemours, to Elizabeth (Betsy) Behl, U.S. EPA (May 25, 2022).] HFPO-DA was developed by one company as a replacement for PFOA's use as a polymerization aid; that industrial process is HFPO-DA's sole use by Chemours, and the only use for which it is legally authorized.[FN28: Id.] As a result, HFPO-DA did not replace PFOA's wide variety consumer-facing applications.[FN29: Id.] And in fact, studies show that no significant exposure levels of HFPO-DA have been found in such consumer-facing products.[FN30: Letter and Attachments from Sheryl Telford, Chemours, to Elizabeth (Betsy) Behl, U.S. EPA (May 31, 2022).]

In sum, there is simply no scientific basis for EPA's 20% RSC for HFPO-DA, as data overwhelmingly show that any HFPO-DA exposure occurs through drinking water and not through other sources. The data support the use of a RSC value of at least 80% within the context of EPA's guidance range.

EPA Response: Please see section 4.3.3 of the EPA response in this *Response to Comments* document. For comments related to dose additivity and the Hazard Index approach, please see sections 4.3.1 and 4.3.2, respectively, of the EPA response in this *Response to Comments* document.

With respect to Chemours' previous submissions to the EPA regarding the toxicity assessment, RSC, and HA, these submissions were not submitted to the EPA as part of this public comment process for this PFAS NPDWR and were instead provided to EPA by the commenter in a different context. Because they were not submitted during the public comment period and the commenter only referred to the documents and did not re-iterate the content of the referred documents in its comment letter for this rule, EPA is not obligated to address them as part of this rulemaking. Nevertheless, to the extent that the EPA could locate these referred documents, the EPA reviewed them and considered whether the issues within were addressed elsewhere in this *Response to Comments* document.

- January 13, 2022 presentation slides from Chemours meeting with EPA Office of Water.
    - The EPA has reviewed these slides related to development of the HFPO-DA RfD (e.g., regarding the critical effect, application of uncertainty factors, MOA), and all comments have been addressed. See EPA Essay Response 4.3.3 and preamble section III.

    - The EPA reviewed this submission which includes a study protocol related to MOA; see the EPA Essay Response 4.3.3 and preamble section III.
- May 31, 2022 letter from Sheryl Telford, Chemours, to Betsy Behl, EPA, and attached studies
    - The EPA reviewed this letter and attached studies related to RSC. See below EPA response to Part B.
- February 7, 2023 email from Sheryl Telford, Chemours, to Betsy Behl, EPA, with attached studies
    - The EPA reviewed this submission, which included four studies: Lea et al. 2022.; Heintz et al. 2022; Heintz et al. 2023; Thompson et al. 2023. The EPA has reviewed all of these studies; please see section 4.3.3 of the EPA response in this *Response to Comments* document and the EPA response to comment Doc. #1845, SBC-046064 in section 4.3.3 in this *Response to Comments* document.

Response to Part A of comment: As the commenter points out, their perceived issues with the HFPO-DA toxicity assessment related to non-PPAR-alpha modes of action, the NTP PWG's evaluation criteria, the constellation of liver lesions, supposed epidemiological evidence, and inflated uncertainty factors were detailed in the Chemours' March 18, 2022 Request for Correction Letter. However, the commenter fails to mention that the EPA denied Chemours' request for correction (which was submitted by Arnold & Porter (A&P) on Chemours' behalf) because "the scientific information described in this [request for correction] would not alter the conclusions of the GenX chemicals toxicity assessment. The EPA does not find that the A&P submission identified errors in the 2021 toxicity assessment or that the process used by EPA was flawed. The points raised by A&P have either been considered and addressed during the peer review process for the GenX chemicals toxicity assessment or would not meaningfully impact the assessment." It is important to note that the EPA provided detailed responses to each of these critiques in 2022 in EPA's Response to RFC 22001 (https://www.epa.gov/system/files/documents/2022-06/RFC_22001_Response_June2022.pdf). Please see section 4.3.3 of the EPA response in this *Response to Comments* document for EPA's reconsideration of these same issues as part of the rulemaking process.

With respect to the quoted language from Dr. Warren's response in the *second* external peer review of the HFPO-DA toxicity assessment, the EPA provided a detailed response to Dr. Warren in its response to peer review on pages 22-23 (https://www.epa.gov/system/files/documents/2021-10/epa_2nd-response-to-peer-review_genx_508.pdf). Additionally, Dr. Warren used comparisons between the values of the HFPO-DA RfD and the PFOA/PFOS RfDs derived in 2016 to justify his remarks that the application of a composite UF of 3,000 is "an extreme application of the precautionary principle." As the EPA pointed out at the time, "altering the UFs to achieve an RfD for GenX chemicals that is closer to the RfDs derived for perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) is not in line with EPA guidance. It is not surprising that more uncertainty is associated with GenX chemicals given their more recent (2015) detection in drinking water. PFOA and PFOS have been extensively studied in the peer reviewed literature for at least the past 30 years and the toxicological data for these chemicals is quantitatively large and comprehensive when compared to the GenX chemicals toxicological database" (USEPA, 2021i). Additionally, the updated RfDs for PFOA and PFOS (USEPA, 2024i and USEPA, 2024k), which postdate the 2021 HFPO-DA toxicity assessment, are orders of magnitude lower than the HFPO-DA RfD, therefore making Dr. Warren's argument moot.

Finally, with respect to the additional scientific studies sponsored by Chemours, please see section 4.3.3 of the EPA response in this *Response to Comments* document.

Response to Part B of comment: Please see section 4.3.3 of the EPA response in this *Response to Comments* document as well as the Hazard Index MCLG support document (USEPA, 2024h) for a complete description of the RSC determination process for HFPO-DA, which was consistent with EPA methodology (USEPA, 2000c).

Regarding the comment criticizing EPA's reference to a Clean Water Act document describing EPA's standard procedure for considering the relative source contribution (USEPA, 2000c), that document explicitly stated that it was adopting EPA's use of relative source contributions under the SDWA to provide a uniform approach to risk assessment in the Office of Water. iIn response to the commenter's statement that the commenter previously provided the EPA with 22 documents (i.e., websites, slides, reports) containing exposure data for HFPO-DA: These 22 documents were not provided to the EPA as part of this public comment process for this PFAS NPDWR and were instead provided to EPA by the commenter in a different context; therefore, the EPA is not obligated to address them as part of this rulemaking. At the time when these 22 documents were provided to EPA, the EPA reviewed them for inclusion in the RSC analysis for HFPO-DA during the development of the draft HFPO-DA MCLG and HBWC for the PFAS rule proposal (US EPA, 2023). Nevertheless, the EPA considered these 22 documents a second time within this rule making context for potential inclusion in the RSC analysis. Ten of the 22 documents had already been considered as part of the EPA's RSC derivation process for the proposed HFPO-DA MCLG and HBWC. The EPA's re-review found that others were unsuitable for inclusion in the RSC derivation process for this final rule, as described in Table 4. Based on the EPA's re-review, three additional documents were included by the EPA as part of RSC

derivation for the final HFPO-DA MCLG and HBWC, but none made a quantitative impact on the RSC determination. The table below presents summary information about the 22 documents that were provided, and whether they were included in the RSC derivation process for HFPO-DA in the final rule.

Table 4. Disposition of the EPA's Review of 22 Documents Provided by Chemours in 2022

Wang et al. 2022. Concentrations of Hexafluoropropylene Oxide Dimer Acid (HFPO DA) in Environmental Media in the US (in prep). Wang et al. 2022. Concentrations of Hexafluoropropylene Oxide Dimer Acid (HFPO DA) in Environmental Media in China (in prep).	No; Excluded because these 5- to 6-page data reports, contain incomplete reporting descriptions of exposure findings and lack information about methods, and are not readily publicly available (i.e., only found online via exact title search, and hosted on website of unknown authority/reputability [static1.squarespace.com]).

With regard to the comment related to the use of HFPO-DA as compared to PFOA, HFPO-DA was developed by one company (Chemours) as a replacement for PFOA's use as a polymerization aid. For the Chemical Data Reporting for the 2020 reporting year, Chemours was the sole company that reported the manufacture or import of HFPO-DA, which was reported to be used as a processing aid. Chemical usage information may inform RSC derivation, and it is especially important when there are no occurrence data for a particular chemical. In the case of HFPO-DA, there is some occurrence information available, and these data suggest that there are several relevant HFPO-DA exposures and pathways beyond drinking water, including dietary consumption, incidental oral consumption via dust and soil or dermal exposure via soil and dust, and inhalation exposure via ambient air (USEPA, 2024h). Several of these may be potentially significant exposure sources to people in the US. Following the EPA's longstanding, peer-reviewed approach for deriving the RSC of the Exposure Decision Tree (USEPA, 2000c), the EPA determined that an RSC of 20 percent (0.20) was appropriate to calculate the HFPO-DA MCLG and HBWC.

4.3.4 Number of Significant Digits

Summary of Major Public Comments and EPA Responses

The EPA received comments on the number of significant digits used for the HBWCs and the Hazard Index MCLG (and MCL). Commenters noted the importance of clearly communicating the number of significant digits to be used in the documents, and that the choice of the number of significant digits could impact implementation of an MCL based on the Hazard Index. A few commenters did not support more than a single significant digit for the HBWCs and Hazard Index MCLG (and Hazard Index MCL), with some stating that using two or more significant digits for the Hazard Index contradicts the EPA chemical mixtures guidance (USEPA, 2000b and USEPA, 1991c). A few commenters supported the use of two significant digits for the HBWCs,

individual HQs, and the Hazard Index MCLG and stated that the use of two significant digits would not be expected to result in issues related to analytical methods precision. One commenter supported using all digits of precision in calculations but rounding to two significant digits for the final reported value of the Hazard Index, noting that the number of significant digits used only affects rounding during steps prior to the point at which a Hazard Index MCL is reached. The EPA response to comments on these issues, as well as others expressed by individual commenters, are described in further detail below. The agency further notes that since the Hazard Index level is set at the MCLG, the EPA responses to comments pertaining to the use of significant figures for the Hazard Index MCL are applicable to those commenters as well. For additional discussion on the PFAS Hazard Index MCL, please see section 5.2 of the EPA response in this *Response to Comments* document.

The EPA proposed a Hazard Index MCLG of 1.0, expressed with two significant digits. The EPA's proposal expressed the HBWCs to the tenths place, as follows: 9.0 ppt for PFHxS, 10.0 ppt for HFPO-DA; 10.0 ppt for PFNA; and 2000.0 ppt for PFBS. The EPA's draft Hazard Index MCLG support document expressed all of the HBWCs with one significant digit (9, 10, 10, 2000 ppt, respectively) (USEPA, 2023o).

For the final rule, the EPA agrees with commenters who did not support more than a single significant digit for the HBWCs and Hazard Index MCLG (and Hazard Index MCL). The EPA has determined that one (1) significant digit is appropriate for the HBWCs (i.e., 10 ng/L each for PFHxS, PFNA, and HFPO-DA and 2000 ng/L for PFBS), the Hazard Index MCLG (and Hazard Index MCL) (i.e., a Hazard Index MCL and MCLG of 1 rather than 1.0), and for the individual MCLGs (and individual MCLs) for PFHxS, PFNA, and HFPO-DA. The HBWCs/MCLGs have one significant digit because although there is sufficient analytical precision to measure to the tenths place in parts per trillion (nanograms per liter) (as described in section 5.1.7 of this *Response to Comments* document), the toxicity reference values (RfDs and minimal risk levels) used to derive these values have one significant digit. In this final rule, the EPA is following the generally accepted practice of rounding the number of significant figures at the end of a calculation to the same number of significant figures in the least precise parameter (in this case, the RfD) (USEPA, 2000a; APHA, 1992; Brinker, 1984). The general rule is that for multiplication or division, the resulting value (in this case, the HBWC/MCLG) should not possess any more significant figures than is associated with the factor in the calculation with the least precision (in this case, the RfD) (USEPA, 2000a). The agency also considered the requirement under SDWA that an MCL must be set as close as feasible to the MCLG. Specific to the Hazard Index, according to the EPA chemical mixtures guidance (USEPA, 2000b), "Because the RfDs (and by inference the TTDs) are described as having precision no better than an order of magnitude, the HI should be rounded to no more than one significant digit." This approach of using a Hazard Index of 1 is consistent with agency chemical mixtures guidance (USEPA, 1986; 2000b) and Superfund risk assessment guidance (USEPA, 1991c; USEPA, 2018c). The EPA's *Risk Assessment Guidance for Superfund Volume 1 Human Health Evaluation Manual* states, "For noncarcinogenic effects, a concentration is calculated that corresponds to an HI of 1, which is the level of exposure to a chemical from all significant exposure pathways in a given medium

below which it is unlikely for even sensitive populations to experience adverse health effects," and "The total risk for noncarcinogenic effects is set at an HI of 1 for each chemical in a particular medium" (USEPA, 1991c). Also, "Cancer risk values and hazard index (HI) values may express more than one significant figure, but for decision-making purposes one significant figure should be used" (USEPA, 2018c).

Individual Public Comments and EPA Responses

Philadelphia Water Department (PWD) (Doc. #1709, SBC-045748)

12. EPA requests comments on the derivation of the HBWC for each of the four PFAS considered and on significant figures.

In section IV.A, In the explanation for the determination of MCLG (and HBWC) values, EPA defines the formula for calculating the MCLG based on the Reference Dose (RfD), drinking water intake-body weight (DWI-BW), and Relative source criteria (RSC) as:

[Equation 1: see docket ID EPA-HQ-OQ-2022-0114-1709]

In section V.C.2 of the preamble of the proposed rule, EPA defines the RfD and DWI-BW for the four PFAS compounds included in the Hazard Index. The calculations are further detailed in rulemaking reference USEPA 2023a, with step-by-step calculation of each of the four HBWCs. Throughout the preamble of this rulemaking, supporting reference documents, and in the rulemaking itself, there is inconsistent use of significant figures for the HBWC values. In the proposed rulemaking, the proposed HBWC values are reported as 9.0 ppt, 10.0 ppt, 10.0 ppt, and 2000.0 ppt. However, in USEPA 2023a, the calculated HBWC values in mg/L are rounded to a single significant figure (i.e., for PFNA 0.000014 mg/L is rounded to 0.00001 mg/L). When the value is converted to ppt it is shown in USEPA 2023a as 10 ppt (equivalent to 0.000010 mg/L) and in the proposed rulemaking as both 10 ppt (equivalent to 0.000010 mg/L) and 10.0 (equivalent to 0.0000100 mg/L). EPA should remain consistent in their use of significant figures and not add additional significant figures after the number is rounded and converted to parts per trillion. The number of significant figures used in the rulemaking has significant impacts on how results are reported (always in mg/L) and how many significant figures are used and how rounding is handled. PWD requests that EPA remain consistent in its use of significant figures throughout the document and clearly define how many significant figures should be used when calculating compliance values. A few specific examples of significant figure inconsistencies are shown in Table 1.

Furthermore, using the values provided in section V.C.2 and USEPA 2023a and the equation shown above, the calculated MCLG/HBWC differ from those proposed in the rulemaking and those that are shown in USEPA 2023a. For example, in USEPA 2023a, the HBWC equation for PFHxS is shown on page 16 to be calculated as 0.0000092 mg/L (then rounded to 0.000009 mg/L and then converted to 9.0 ppt). However, when the numbers are calculated as shown in

USEPA 2023a, the correct output for the PFHxS HBWC is 0.000012 mg/L, which would round to 0.00001 mg/L (or 10 ppt) rather than 9.0 ppt.

PWD requests that if the HI requirement is kept in place, that the HBWC values be updated to match their correctly calculated values using a consistent number of significant figures.

Table 1 Examples of inconsistent significant figures for HBWC values throughout the rulemaking and supporting documents

[Table 1: See Docket ID EPA-HQ-OW-2022-0114-1709]

EPA Response: Please see section 4.3.4 of the EPA response in this *Response to Comments* document.

Connecticut Department of Public Health (CT DPH) (Doc. #1745, SBC-045210)

CT DPH also noticed that the number of significant figures EPA uses in the preamble for the same value is not consistent. For example, "In this proposal, the HBWCs that EPA uses to calculate the HI are proposed to be 9.0 ppt for PFHxS; 10.0 ppt for HFPO-DA; 10.0 ppt for PFNA; and 2000 ppt for PFBS (USEPA, 2023a). " (P18669) "the HBWC for HFPO–DA is 10.0 ppt; the HBWC for PFNA is 10 ppt; the HBWC for PFBS is 2000.0 ppt". If the differing use of significant figures is intentional, EPA should clarify whether they intend the same precision to be used for the analytical results when the results are used for HQ/HI calculation. If the levels of precision were not meant to be different, CT DPH recommends EPA use a consistent number of significant figures use for the same value.

EPA Response: Please see section 4.3.4 of the EPA response in this *Response to Comments* document.

Minnesota Pollution Control Agency (MPCA) (Doc. #1569, SBC-042492)

2) EPA requests comment on significant figure use when calculating both the HI MCLG and the MCL. EPA has set the HI MCLG and MCL using two significant figures (i.e., 1.0). EPA requests comment on the proposed use of two significant figures for the MCLG when considering underlying health information and for the MCL when considering the precision of the analytical methods.

MPCA response:

• MPCA supports the use of 2 significant figures for the MCLs/MCLGs.

EPA Response: Please see section 4.3.4 of the EPA response in this *Response to Comments* document.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-044022)

5. EPA requests comment on significant figure use when calculating both the HI MCLG and the MCL. EPA has set the HI MCLG and MCL using two significant figures (i.e., 1.0). EPA requests comment on the proposed use of two significant figures for the MCLG when considering underlying health information and for the MCL when considering the precision of the analytical methods.

a. CWUC agrees that two significant figures is appropriate for all HI/MCLs. If the PQL, MCL, and trigger levels for all the other PFAS parameters use two significant figures, then the HI should also use two significant figures.

EPA Response: Please see section 4.3.4 of the EPA response in this *Response to Comments* document. For a discussion of significant digits for the PQLs, please see section VII of the final rule preamble; for the PFOA and PFOS MCLs, please see section V of the final rule preamble and section 5.1.7 of the EPA response in this *Response to Comments* document; for trigger level values, please see section VIII of the final rule preamble.

Nebraska Department of Environment and Energy (NDEE) (Doc. #1653, SBC-043206)

If the Hazard Index is retained in the final rule, the significant figure used in the HI should be consistent with the MCLs. Using one significant figure would be consistent with other chronic rules.

EPA Response: Please see section 4.3.4 of the EPA response in this *Response to Comments* document.

American Chemistry Council (ACC) (Doc. #1841, SBC-052935)

The numerical examples provided by the EPA to illustrate the application of the proposed MCLGs to an HI of two significant digits (i.e., 1.0) [FN156: 88 Fed. Reg. 18664-18665.] contradict the Agency's own long standing regulatory guidance and practice, and basic mathematical rounding rules.

The USEPA provides examples of applications of the PFAS HI method in which results are expressed and interpreted to two significant digits with the target threshold stated as Hazard Quotient(HQ) >1.0, rather than the standard HQ>1. [FN157: It is noteworthy that the PFAS Mixtures Framework document generally refers to HI>1 as the accepted threshold, except in the section where it introduces the examples.] This contradicts the Risk Assessment Guidance for Superfund, in which USEPA established that the rationale for rounding noncancer hazard quotients (HQ) to one significant digit is that the toxicity values (e.g., RfDs) are limited to one significant digit. [FN158: USEPA. Risk Assessment Guidance for Superfund (RAGS), Volume I, Human Health Evaluation Manual (Part A). EPA/540/I-89/002. Office of Emergency and Remedial Response (1989).] Furthermore, the exposure factors used in the calculation of the HBWQs are also rounded to one significant digit. Therefore, the use of two significant digits is inconsistent with EPA guidance and standard practice, and basic mathematical rules of rounding.

EPA should have recommended performing calculations with individual HQs expressed to 2 significant digits, but the final answer (HI) should be rounded to one significant digit.

EPA Response: The EPA agrees that the final Hazard Index should be rounded to one significant digit. Please see section 4.3.4 of the EPA response in this *Response to Comments* document.

Missouri Department of Natural Resources (Doc. #1563, SBC-052826)

EPA requests comment on significant figure use when calculating both the HI MCLG and the MCL. EPA has set the HI MCLG and MCL using two significant figures (i.e., 1.0). EPA requests comment on the proposed use of two significant figures for the MCLG when considering underlying health information and for the MCL when considering the precision of the analytical methods.

From the Department's review, it does not appear that EPA is consistent in their use of two significant figures when setting the MCLs. As stated in the preamble, "Under section 1412(b)(4)(B) of SDWA, EPA must generally establish an enforceable MCL as close to the MCLG as is feasible, taking costs into consideration. The Agency evaluates feasibility according to several factors including the availability of analytical methods capable of measuring the targeted compounds in drinking water and examining available treatment technologies capable of contaminant removal examined under laboratory and field conditions." In § 141.40 Monitoring requirements for unregulated contaminants, the EPA defines in CFR 141.40(a)(5)(iii) the minimum reporting level (MRL) as "the quantitation limit achievable, with 95 percent confidence, by 75 percent of laboratories nationwide, assuming the use of good instrumentation and experienced analysts". In establishing the MRL, EPA refers to the Unregulated Contaminant Monitoring Rule (UCMR 5) where EPA set the MRL for PFOA and PFOS with one significant figure at 0.004 µg/L. The preamble indicates 0.004 µg/L is equal to the two significant figures in 4.0 ppt, which is not accurate. It is also not accurate that EPA based the proposed 0.0040 µg/L MCL on meeting 95 percent confidence by 75 percent of laboratories nationwide. As stated in the UCMR 5 Laboratory Approval Manual, Version 2.0 from December 2021, seventeen labs participated in the LCMRL [Lowest Concentration Minimum Reporting Level] studies that generated the data in the Appendix B tables. The calculated MRL values in Appendix B, Table 19 were based on a minimum of three LCMRL values from the participating laboratories and appear to have only been based on eight or fewer labs out of 17, and not on required actual participation as defined in 141.40(a)(5)(iii) as 75 percent of labs nationwide.

EPA Response: Please see sections 4.3.4 and 5.2 of the EPA response in this *Response to Comments* document.

4.3.5 Incorporating Additional PFAS

Summary of Major Public Comments and EPA Responses

Commenters had questions or comments about the process for adding additional PFAS to the Hazard Index. Many commenters urged the EPA to consider making a determination to regulate for additional PFAS (in a mixture) or all PFAS as a class. A few commenters expressed concern that the EPA would add PFAS to the Hazard Index without making a determination to regulate consistent with the SDWA. The EPA response to comments on these issues, as well as others expressed by individual commenters, are described in further detail below.

The agency is required to demonstrate a contaminant meets the SDWA statutory criteria to make a regulatory determination. In addition to PFOA and PFOS which the EPA has already made a final determination to regulate individually, the agency is making final determinations for the four PFAS with sufficient information, including available health assessments, occurrence data, and meaningful opportunity information, to meet these statutory criteria individually and/or as part of mixture combinations. Using this available information, the agency followed the SDWA regulatory process and determined that three of these PFAS—PFHxS, PFNA, HFPO-DA, and mixtures of these three PFAS and PFBS—may cause adverse human health effects; are likely occur and/or co-occur in PWSs with a frequency and at levels of public health concern; and in the sole judgment of the Administrator, regulation presents a meaningful opportunity for health risk reductions for people served by PWSs. Some commenters suggested that the EPA consider regulating some additional PFAS, including perfluorobutanoic acid (PFBA), PFDA, PFHpA, and Perfluorohexanoic acid (PFHxA), as part of this rulemaking. As required under the statute, to make a regulatory determination the EPA must demonstrate that the three statutory criteria have been met which is informed by the best available information. The EPA focused on PFHxS, PFNA, HFPO-DA, and mixtures of these three PFAS and PFBS because there is sufficient information for these PFAS to allow for timely evaluation of them for regulation as part of this action. In addition, at the time of the EPA's review of available information, the EPA did not have adequate health and occurrence information to develop a total PFAS MCL.

The EPA's final regulatory determination and final rule are limited to mixtures that include two or more of PFNA, PFHxS, PFBS, and HFPO-DA. If there is any potential future inclusion of additional PFAS under this approach (e.g., individual PFAS or as a "class," precursor PFAS), such inclusion would be the subject of a potential future regulatory process under SDWA (please see section 5.1.6 of the EPA response in this *Response to Comments* document for more information). As information becomes available, the agency will continue to evaluate other PFAS for potential future preliminary regulatory determinations. Please see section 3 of the EPA response in this *Response to Comments* document and section III of the preamble for this action for further discussion about regulatory determinations.

Individual Public Comments and EPA Responses

Orange Water and Sewer Authority (OWASA) (Doc. #1524, SBC-042623)

• Future PFAS to be added to the regulation

o OWASA has to assume that other PFAS may be added to the regulation in the future and install treatment that not only works for PFOS and PFOA but shorter chain PFASs should they become regulated in the future too – we can't ask our rate payers to install $50M worth of treatment only to have it not be enough in the next few years when a new regulation may be passed

Ways to post our comments:

EPA Docket - https://www.regulations.gov/docket/EPA-HQ-OW-2022-0114/document

EPA May 4th public hearing -

WUC – Allison to send comments to Steve Via

EPA Response: Please see sections 4.3.5 and 13 of the EPA response in this *Response to Comments* document.

New York City Department of Environmental Protection (NYCDEP) (Doc. #1679, SBC-044206)

Additionally, it is assumed that the HI calculation will change over time to include more chemicals meeting the definition (a level at which no known or anticipated adverse effects on the health of persons is expected to occur, p. 18638). Typically, the water industry has produced occurrence data over a long period of record, allowing for assessment of trends and effectiveness of mitigations. As the HI calculation changes, the meaning of the HI will change, and not be available or appropriate for trend detection, compared to the more traditional regulatory approach.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Linda Shosie (Doc. #1533, SBC-043966)

We strongly believe that the establishment of new MCLs for PFAS is essential to ensure that our drinking water is safe. These new regulations will provide a clear standard for water utilities and other organizations to follow and will ensure that they are taking appropriate steps to remove PFAS from our water supply. With over 11,000 of these toxic chemicals in the PFAS class, we cannot do these one or two chemicals at a time. This will need to be done as a class.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Michigan Department of Environment, Great Lakes, and Energy (EGLE) Drinking Water and Environmental Health Division (DWEHD) (Doc. #1597, SBC-042972)

Consistent with Michigan's regulatory determination, EGLE DWEHD recommends that EPA consider including PFHxA, in addition to those four PFAS compounds proposed in the NPDWR, based on those same three statutory requirements established by the SDWA:

1. Some people who drink water containing PFHxA in excess of Michigan's MCL could experience adverse health effects. For the purpose of developing Michigan's PFHxA MCL, an independent panel of scientists determined that current toxicity data was sufficient and utilized a risk assessment based specifically on renal effects.1 [REF1: Health-Based Drinking Water Value Recommendations for PFAS in Michigan, a Report by the Michigan Science Advisory Workgroup, July 2019.]

2. Michigan's statewide PFAS survey results (2018 – 2020) indicate that PFHxA occurred in 10% of samples, and compliance monitoring results (2020 – present) indicate that PFHxA occurs in 4.1% of samples.

3. The regulation of PFHxA represents a meaningful opportunity for health risk reduction. EPA-approved analytical methods, treatment technologies, and achievable steps to manage drinking water all exist and are available to meet this challenge.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Lehigh County Authority (LCA) (Doc. #1600, SBC-042811)

4. Future Implications – As EPA is well aware, the family of PFAS compounds ranges in the thousands. How will the Hazard Index approach be adjusted over time to accommodate new PFAS compounds that are added to future regulations?

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Colorado Water Utility Council (CWUC) (Doc. #1622, SBC-044021)

e. Finally, any future additional parameters considered for inclusion in the HI (or MCL) must go through the required assessment evaluation and public input process.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

GFL Environmental (Doc. #1648, SBC-043222)

The EPA has stated they may consider the HI approach for additional PFAS as health hazard information becomes available, yet the formal process by which new PFAS are added to the HI has not been clearly defined and there is concern that the process is not as robust as that currently required by SDWA.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Blue Ridge Environmental Defense League (BREDL) (Doc. #1663, SBC-044381)

May 29, 2023

Docket ID No. EPA-HQ-OW-2022-0114

U.S. Environmental Protection Agency

EPA Docket Center

Office of Ground Water and Drinking Water Docket

Mail Code 2822IT

1200 Pennsylvania Avenue, NW

Washington, DC 20460

Comments on EPA Docket ID No. EPA-HQ-OW-2022-0114 PFAS National Primary Drinking Water Regulation Rulemaking

To Whomever it May Concern:

On behalf of Blue Ridge Environmental Defense League (BREDL) I am submitting these comments on the proposed drinking water limits for six PFAS compounds: PFOA. PFOS, GenX, PFBS, PFHxS, and PFNA (the six). This is an important step; however, PFAS must be regulated as a class in order to protect public health.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Washington State Department of Health (DOH) (Doc. #1665, SBC-044405)

EPA requests comment on whether there are other peer-reviewed health or toxicity assessments for other PFAS the Agency should consider as a part of this action.

• PFBA has a completed toxicity value. EPA should consider adding it to the HI approach or as an individual MCL. This action should consider whether sufficient laboratory capacity is available since establishing an MCL for PFBA would force water systems to use test method 533. Method 531.7 does not measure PFBA.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Aurora Water, City of Aurora, Colorado (Doc. #1669, SBC-043709)

The current proposed rule allows for the addition of other PFAS compounds to the HI calculation as the EPA sees fit. Aurora does not agree with EPA having the ability to add new chemicals to the HI without the proper rulemaking process. Allowing for an open- ended HI definition is unfair to water systems as the rule would continue to change without proper notice or public input as prescribed under the Safe Drinking Water Act. Additionally, as more compounds are added, the HI ratios will need to be recalculated so compliance with the HI MCL can continuously be achieved. Aurora is insisting EPA follows proper procedure when adding any PFAS compounds to future HIs and they reconsider the ratios of compounds during each rulemaking process.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Rockbridge Area Conservation Council (RACC) (Doc. #1678, SBC-044299)

3) EPA Statement:

"The Hazard Index (HI) is a commonly used risk management approach for mixtures of chemicals (USEPA, 1986a; 2000a). In this approach, a ratio called a hazard quotient (HQ) is calculated for each of the four PFAS (PFHxS, HFPO-DA and its ammonium salt (also known as GenX chemicals), PFNA, and PFBS) by dividing an exposure metric, in this case, the measured level of each of the four PFAS in drinking water, by a health reference value for that particular PFAS. For health reference values, in this proposal, EPA is using Health Based Water Concentration (HBWCs) as follows: 9.0 ppt for PFHxS, 10.0 ppt for HFPO-DA; 10.0 ppt for PFNA; and 2000 ppt for PFBS (USEPA, 2023a). The individual PFAS ratios (HQs) are then summed across the mixture to yield the HI. If the resulting HI is greater than one (1.0), then the exposure metric is greater than the health metric and potential risk is indicated. EPA's Science Advisory Board (SAB) opined that where the health endpoints of the chosen compounds are similar, it is reasonable to use an HI as "a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media." (USEPA, 2022a)."

The idea of using a group "HI" for the chemicals noted above maybe useful for those four analytes, however, it does not address the other PFAS chemicals that can be identified in 98% of Americans blood, wildlife, consumer/industrial products, and/or the environment (land/water/air). With that said, using total PFAS levels in an HI calculation may be a much better choice, at least for the number of analytes used in the current EPA 1633 method. Realizing that not enough safety data may exist for all analytes to be included based on the ability to cause health effects … chemical toxicity can be estimated based on structurally similarities to other known toxic PFAS chemicals via carbon lengths, molecular weight, endocrine disruption activity … etc., to estimate a "no effect level". Additionally, using the current regulatory system(s) to review all 10,000+ PFAS analytes individually would be a task that would require generations to complete and would continue to allow PFAS to wreak havoc in people's lives. Regardless, of

how the PFAS materials are grouped, the issue of cumulative and/or synergistic interactions between PFAS chemicals – especially among those with endocrine disruptive activity - is ignored in this proposal.

Therefore, we respectfully request that using a total PFAS level in addition to or instead of the grouping of the 4 PFAS noted above, to add back some of the safety margins that have been removed by the analytical shortfalls adopted to justify the MCL of 4 ppt for PFOA/PFOS.

When dealing with estimating the adverse effects of PFAS or any other toxic chemical, it is always good to understand that toxicology and protection of public health require that a chemical be viewed as guilty until proven innocent, not the other way around. For compounds like PFAS that persist, bioaccumulate, and bioconcentrate in the environment, this is more than a best practice, it is essential. Wang, et al. (2017) observes that:

The most common current industrial practice of phasing out one PFAS is to replace it with another (or multiple other) structurally similar PFAS. Such a strategy is easier and less costly than identifying a nonfluorinated substance to be used in the same or similar process (i.e., chemical replacement) or inventing a new process that does not require PFASs (i.e., functionality replacement)..... [B]ut such a replacement strategy will not solve issues in relation to PFASs as a whole group—it will only increase the numbers of PFASs on the market and the difficulties in tracking them.

Promulgating individual PFAS compound standards until all 10,000+ compounds can be studied is an impossible task. Until there is an MCLG of zero for total PFAS in drinking water that disincentivizes the use of new or different PFAS without comprehensive health effect studies, the Agency cannot adequately control exposure to PFAS. We recommend that the PFAS MCLG of zero apply to all PFAS compounds that have no higher proven safe limit.

We hope that these comments will support EPA's admirable continuing advances in eliminating the impact of PFAS on human health and the environment.

Most sincerely,

Barbara Walsh, Executive Director Rockbridge Area Conservation Council (RACC)

Zhanyun Wang et al., "A Never-Ending Story of Per- and Polyfluoroalkyl Substances (PFASs)?," Environmental Science & Technology 51, no. 5 (March 7, 2017): 2508–18, https://doi.org/10.1021/acs.est.6b04806. Copyright 2017 American Chemical Society.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Wisconsin Department of Justice et al. (Doc. #1687, SBC-044450)

6. After finalizing the PFAS Rule, EPA should consider drinking water standards for other PFAS both alone and in combination.

The States applaud EPA for taking this important step to regulate and set MCLs and MCLGs for PFOA, PFOS, PFHxS, GenX, PFNA, and PFBS. However, there are other PFAS that EPA should consider for regulation to protect human health. For example:

• The Massachusetts Department of Environmental Protection has adopted MCLs for six PFAS, including two PFAS not addressed by the proposed PFAS Rule: perfluorodecanoic acid (PFDA) and perfluoroheptanoic acid (PFHpA). [FN47: Development of a PFAS Drinking Water Standard (MCL) (mass.gov) (last visited May 4,2023)]

• The Wisconsin Department of Health Services recommended groundwater standards for the protection of public health for 12 PFAS in addition to the PFAS regulated in the proposed PFAS Rule. [FN48: https://dnr.wisconsin.gov/sites/default/files/topic/PFAS/DHSCycle11Letter20201106.pdf (last visited May 3, 2023).]

• New York has proposed drinking water standards for two PFAS not addressed by the proposed PFAS Rule: PFDA and PFHpA. [FN49: XLIV N.Y. Reg. 16-20 (Oct. 5, 2022).]

• The Michigan Department of Environment, Great Lakes, and Energy has adopted MCLs for seven PFAS, including all of those in EPA's proposed standards and one PFAS not addressed by the proposed PFAS Rule: perfluorohexanoic acid (PFHxA). [FN50: Michigan PFAS Action Response Team, Maximum Contaminant Levels (MCLs), https://www.michigan.gov/pfasresponse/drinking-water/mcl (last visited May 26, 2023).]

• EPA released or plans to release Integrated Risk Information System Toxicological Reviews for perfluorobutanoic acid (PFBA), PFHxA, and PFDA. [FN51: EPA, Toxicological Review of Perfluorobutanoic Acid (PFBA) and Related Salts (Final Report 2022), https://cfpub.epa.gov/ncea/iris_drafts/recordisplay.cfm?deid=356425; EPA, Toxicological Review of Perfluorohexanoic Acid (PFHxA) and Related Salts (Final Report 2023), https://cfpub.epa.gov/ncea/iris_drafts/recordisplay.cfm?deid=357314; EPA, Toxicological Review of Perfluorodecanoic Acid (PFDA) and Related Salts (Draft Report 2023),https://cfpub.epa.gov/ncea/iris_drafts/recordisplay.cfm?deid=354408.]

These regulatory actions support additional, broader federal drinking water regulations. EPA should actively review additional PFAS, and groups of PFAS, as viable targets for future enforceable drinking water standards, including setting MCLGs and MCLs for additional PFAS beyond the six in the proposed PFAS Rule. The undersigned States are available to work with the agency in considering for regulation additional PFAS that pose risks to human health through drinking water exposures.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

New Hampshire Department of Environmental Services (NHDES) (Doc. #1690, SBC-044342)

Section IV, Part B. Page 18,655, Column 2, 1st Paragraph. - EPA also considered setting individual MCLGs instead of and in addition to using a mixtures-based approach for PFHxS, HFPO–DA, PFNA, and/or PFBS in mixtures. … EPA is seeking comments on the merits and drawbacks of each of the approaches described above. As discussed later in this proposal, EPA is also seeking comment on whether to set MCLGs for the individual PFAS in addition to or instead of setting them for the mixture.

Section IV, Part C.1. Page 18,664, Column 1, 2nd Paragraph. - EPA is seeking comment on derivation of the HBWCs for each of the four PFAS considered as part of the HI.

NHDES Comment - The Hazard Index proposed by EPA includes 4 PFAS (PFBS, PFHxS, PFNA and GenX), but does not include other PFAS for which EPA has developed Reference Doses (RfDs) (i.e, PFBA, PFHxA and a draft for PFDA) (Section V-Maximum Contaminant Level Goal – Page 18656, Column 2). We suggest EPA improve its proposed rule by clarifying issues around 1) EPA IRIS's ongoing assessment of PFHxS and PFNA and 2) exclusion of other PFAS with EPA IRIS RfDs and addressing future PFAS.

EPA should clarify if EPA Office of Water's RfVs (functionally RfDs) for PFHxS and PFNA are essentially applicable as agency wide RfDs for other media, nullifying the necessity of the review process by EPA IRIS. If Office of Water's RfVs for these two PFAS are merely placeholders in the proposed rule, EPA should clarify how these will be updated when EPA IRIS finalizes RfDs and how the resulting Hazard Index would be impacted as EPA IRIS finalizes it assessments of PFHxS and PFNA. Additionally, EPA should clarify if these RfVs are unique only to characterizing toxicity from exposure via drinking water ingestion and whether the agency considers these oral toxicity factors applicable to other exposures via ingestion (e.g., food, dusts, or incidental soil ingestion).

EPA Response: Please see sections 4.3.5 and 4.3.3 of the EPA response in this *Response to Comments* document. With respect to clarifying the use of RfVs in various environmental media, as a general matter, RfVs can be used with exposure information and other important considerations to determine if, and when, it is appropriate to take action to reduce exposure to specific chemicals.

New Hampshire Department of Environmental Services (NHDES) (Doc. #1690, SBC-044344)

During the timeframe that EPA prepared this initial rule proposal, EPA finalized human health risk assessments for PFBA and PFHxA. In the proposed rule for a Hazard Index to cover 4 PFAS, EPA does not explain the exclusion of these two compounds specifically. Understandably, these were finalized while EPA prepared this initial release of a rule making document, but there is no justification relative to occurrence from UCMR 3 (e.g., occurrence was so infrequent that EPA determined regulation was not meaningful) or lack of evidence for dose-additivity for these two as to preclude them or other PFAS from future inclusion into the Hazard Index. As a part of

the response to comments, EPA should clarify how these two will be addressed, as well as other PFAS (e.g., PFDA) that are under review for toxicological assessment and that future UCMR or other occurrence data may report with lower detection/reporting limits. If exclusion of these or other future PFAS is simply a risk management decision, that should be explicitly stated and justified by EPA.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Philadelphia Water Department (PWD) (Doc. #1709, SBC-045746)

10. Potential for additional PFAS compounds not in proposed rule being added as individual MCL or to HI in final rule

In Section III, EPA requests comment on whether there is peer-reviewed information on additional PFAS that EPA should include in this rulemaking. PWD believes that EPA should not add PFAS as individual MCLs or in the HI that were not included in the proposed rule. Doing so would prevent stakeholders from commenting and reviewing the addition of these new compounds and circumvents the overall rulemaking process. PWD recommends that EPA use the standard regulatory determination process to inform rulemaking for any additional PFAS compounds.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Environmental Working Group (EWG) (Doc. #1721, SBC-045418)

After finalizing the rule, EPA should develop drinking water standards for other PFAS.

The EPA should expeditiously finalize the proposed rule, but then should also work to develop drinking water standards for additional PFAS.

An emerging body of evidence shows that many, and likely all PFAS, may cause adverse effects on the human health system. All PFAS persist in the environment and many PFAS build up in the blood and organs. Since 1999, the Centers for Disease Control has monitored at least 12 different PFAS chemicals in blood through the National Health and Nutrition Examination Survey. [FN70: Ctrs. for Disease Control & Prevention, Nat'l Biomonitoring Program, Per- and Polyfluorinated Substances (PFAS) Factsheet, https://www.cdc.gov/biomonitoring/PFAS_FactSheet.html (last updated May 02, 2022).] A 2013 study analyzed the concentrations of 21 different PFAS in autopsy samples from brain, liver, lung, bone, and kidney tissue and found PFAS in all human tissues. [FN71:Francisca Perez et al., Accumulation of Perfluoroalkyl Substances in Human Tissues, 59 ENV'T INT'L 354 (2013), https://pubmed.ncbi.nlm.nih.gov/23892228/.] A March 2020 analysis, led by EWG researchers, applied the Key Characteristics of Carcinogens framework for cancer hazard identification to 26 different PFAS and found that each PFAS displayed at least one of the key characteristics. [FN72: Alexis M. Temkin et al., Application of

Key Characteristics of Carcinogens to Per and Polyfluoroalkyl Substances, 17 INT'L J. OF ENV'T RESEARCH & PUBLIC HEALTH 1668 (2020), https://pubmed.ncbi.nlm.nih.gov/32143379/.] Studies by the National Toxicology Program show that many short-chain PFAS chemicals created to replace their long-chain predecessors are associated with the same or similar toxic effects. [FN73: Nat'l Toxicology Program, Per- and Polyfluoroalkyl Substances (PFAS), https://ntp.niehs.nih.gov/whatwestudy/topics/pfas/index.html (last updated May 19, 2023); See also Cheryl Hogue, Short-Chain and Long-Chain PFAS Show Similar Toxicity, US National Toxicology Program Say, CHEM. & ENG'G NEWS (Aug. 24, 2019), https://cen.acs.org/environment/persistent-pollutants/Short-chain-long-chain-PFAS/97/i33.]

The Agency for Toxic Substances and Disease Registry did a comprehensive study of 14 PFAS in 2018 and found several health effects associated with various PFAS. [FN74: Agency for Toxic Substances & Disease Registry, Toxicological Profile for Perfluoroalkyls (2018) https://www.atsdr.cdc.gov/toxprofiles/tp200.pdf.] More than 20 states have determined that there is adequate health information to initiate regulations or develop health guidelines for various PFAS in drinking water including PFOA, PFOS, GenX, PFBA, PFBS, PFHpA, PFHxS, PFHxA, PFNA, and PFDA. [FN75:Emma Cormier, John Kindschuh, & Thomas Lee, PFAS Update: State-by-State PFAS Drinking Water Standards-February 2023, JD SUPRA (Feb. 21, 2023), https://www.jdsupra.com/legalnews/pfas-update-state-by-state-pfas-3060474/.] Many of the detected PFAS not covered by EPA's proposal are being evaluated by EPA's Integrated Risk Information System, or IRIS, and have toxicity values. The EPA has completed a draft evaluation and toxicity assessment of PFDA [FN76: Env't Prot. Agency, Integrated Risk Information System, IRIS Toxicological Review of Perfluorodecanoic Acid (PFDA) and Related Salts (Public Comment and External Review Draft) (April 2023), https://cfpub.epa.gov/ncea/iris_drafts/recordisplay.cfm?deid=354408.] and a final evaluation and toxicity assessment of PFBA [FN77: Env't Prot. Agency, Integrated Risk Information System, IRIS Toxicological Review of Perfluorobutanoic Acid (PFBA, CASRN 375-22-4) and Related Salts (Dec. 2022), https://cfpub.epa.gov/ncea/iris/iris_documents/documents/toxreviews/0701tr.pdf.] and PFHxA. [FN78: Env't Prot. Agency, Integrated Risk Information System, IRIS Toxicological Review of Perfluorohexanoic Acid [PFHxA, CASRN 307-24-4] and Related Salts (April 2023), https://cfpub.epa.gov/ncea/iris/iris_documents/documents/toxreviews/0704tr.pdf.]

Many PFAS not covered by the proposed rule are ubiquitous in the environment. A recent peer-reviewed, published study of tap water collected from 16 states, including more than 20 samples from public water supplies, detected 26 different PFAS, only six of which are covered by EPA's proposed rule. [FN79: Katherine E. Pelch, Taryn McKnight, & Anna Reade, 70 Analyte PFAS Test Method Highlights Need for Expanded Testing of PFAS in Drinking Water, 876 SCI. OF THE TOTAL ENV'T 162978 (June 2023), https://www.sciencedirect.com/science/article/pii/S0048969723015966.] In 2020, EWG tested 44 tap water samples from 31 states for 30 PFAS and found that all but one sample had detectable levels of PFAS. [FN80: Sydney Evans et al., New Detections of 'Forever Chemicals'

in New York, D.C., Other Major Cities, ENV'T WORKING GRP. (Jan. 23, 2020), https://www.ewg.org/research/national-pfas-testing.] EWG maintains and regularly updates a map with more than 2,800 sites contaminated with PFAS. [FN81:Env't Working Grp., PFAS Contamination in the U.S., https://www.ewg.org/interactivemaps/pfas_contamination/ (last updated June 08, 2022).] The EWG map contains data from the Unregulated Contaminant Monitoring Rule 3, state monitoring data, and Department of Defense monitoring. When the EPA begins releasing UCMR 5 data in mid-2023, there will be additional occurrence data on a wider range of PFAS.

However, SDWA allows for regulation not only where there is known occurrence, but also when there is a substantial likelihood that PFAS will occur in public drinking water at levels of public health concern. In addition to drinking water data, there is a wealth of data on PFAS contamination in surface and ground water. [FN82: 42 U.S.C. 300g-1(b)(1)(A)(ii).] Many of these surface water measurements are taken from or near sources of drinking water, making it likely that drinking water systems are also contaminated. A recent study of U.S. surface waters found 33 PFAS across 29 states and the District of Columbia, with one or more PFAS detected in 83% of the water bodies sampled. [FN83: Waterkeeper Alliance, Invisible, Unbreakable, Unnatural: PFAS Contamination of U.S. Surface Waters 13 (2022), https://waterkeeper.org/wp-content/uploads/2022/10/Waterkeeper-Alliance-PFAS-Report-FINAL-10.14.22.pdf.] A 2020 EWG analysis found that groundwater at military installations is frequently contaminated with eight different kinds of PFAS, including 4 not covered by the proposed MCLs, sometimes in very high concentrations. [FN84: Melanie Benesh, The Pentagon Should Address All Types of PFAS on Military Bases, ENV'T WORKING GRP. (May 26, 2020), https://www.ewg.org/news-insights/news/pentagon-should-address-all-types-pfas-military-bases.]

[Table1: See Docket ID EPA-HQ-OW-2022-0114-1721]

The EPA also has authority to develop MCLs for a class of chemicals, as it has done for total coliforms, haloacetic acids, trihalomethanes, chloramines, and PCBs. SDWA does not require detailed information about every member of a chemical class to develop NPDWRs to protect the public from their cumulative health effects. The EPA could follow the example of the European Union which has established a drinking water standard for "the totality of per- and polyfluoroalkyl substances."[FN85: Eur, Parliament & of the Council on Quality of Water Intended for Human Consumption, Directive (EU) 2020/2184 (Dec. 16, 2020), https://eur-lex.europa.eu/legal-content/EN/TXT/PDF/?uri=CELEX:32020L2184; see also Health Canada, Draft Objective for Per- and Polyfluoroalkyl Substances in Canadian Drinking Water: Rationale (Feb. 10, 2023), https://www.canada.ca/en/health-canada/programs/consultation-draft-objective-per-polyfluoroalkyl-substances-canadian-drinking-water/rationale.html (proposing 30 ppt drinking water limit for combined levels of 18 or more PFAS).]

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Joe DiNardo (Doc. #1725, SBC-045762)

3) EPA Statement:

"The Hazard Index (HI) is a commonly used risk management approach for mixtures of chemicals (USEPA, 1986a; 2000a). In this approach, a ratio called a hazard quotient (HQ) is calculated for each of the four PFAS (PFHxS, HFPO-DA and its ammonium salt (also known as GenX chemicals), PFNA, and PFBS) by dividing an exposure metric, in this case, the measured level of each of the four PFAS in drinking water, by a health reference value for that particular PFAS. For health reference values, in this proposal, EPA is using Health Based Water Concentration (HBWCs) as follows: 9.0 ppt for PFHxS, 10.0 ppt for HFPO-DA; 10.0 ppt for PFNA; and 2000 ppt for PFBS (USEPA, 2023a). The individual PFAS ratios (HQs) are then summed across the mixture to yield the HI. If the resulting HI is greater than one (1.0), then the exposure metric is greater than the health metric and potential risk is indicated. EPA's Science Advisory Board (SAB) opined that where the health endpoints of the chosen compounds are similar, it is reasonable to use an HI as "a reasonable approach for estimating the potential aggregate health hazards associated with the occurrence of chemical mixtures in environmental media." (USEPA, 2022a)."

The idea of using a group "HI" for the chemicals noted above maybe useful for those four analytes, however, it does not address the other PFAS chemicals that can be identified in 98% of Americans blood, wildlife, consumer/industrial products, and/or the environment (land/water/air). With that said, using total PFAS levels in an HI calculation may be a much better choice, at least for the number of analytes used in the current EPA 1633 method. Realizing that not enough safety data may exist for all analytes to be included based on the ability to cause health effects … chemical toxicity can be estimated based on structurally similarities to other known toxic PFAS chemicals via carbon lengths, molecular weight, endocrine disruption activity … etc., to estimate a "no effect level". Additionally, using the current regulatory system(s) to review all 10,000+ PFAS analytes individually would be a task that would require generations to complete and would continue to allow PFAS to wreak havoc in people's lives. Regardless, of how the PFAS materials are grouped, the issue of cumulative and/or synergistic interactions between PFAS chemicals – especially among those with endocrine disruptive activity - is ignored in this proposal.

Therefore, I respectfully request that using a total PFAS level in addition to or instead of the grouping of the 4 PFAS noted above, to add back some of the safety margins that have been removed by the analytical shortfalls adopted to justify the MCL of 4 ppt for PFOA/PFOS.

When dealing with estimating the adverse effects of PFAS or any other toxic chemical, it is always good to understand that toxicology is the direct opposite of democracy … a chemical should always be viewed as guilty until proven innocent … protecting public health "should be" priority one, not industrial profits!

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Rio Grande Waterkeeper and WildEarth Guardians (Doc. #1732, SBC-045424)

II. EPA Should Act Expeditiously to Propose and Adopt New Drinking Water Regulations Addressing a Broad Swathe of PFAS Contaminants

While the proposed rule will begin to protect Americans from drinking these six PFAS substances from their tap, there are thousands more PFAS chemicals that the rule does not cover. As state and federal governments regulate specific PFAS chemicals, industry has and will continue to engage in "regrettable substitutions" by replacing the regulated chemical with an unregulated one that may be equally or more harmful. [FN17: Lindsey Konkel, The P-Sufficient Approach: A Strategy for Regulating PFAS as a Class, ENV'T HEALTH PERSPECTIVES (May 14, 2021), https://doi.org/10.1289/EHP9302.] While the health impacts of all the thousands of PFAS chemicals are not fully understood, scientists warn that limited data should not be used as a justification to delay regulation of replacement PFAS. [FN18: Sunderland, E.M., Hu, X.C., Dassuncao, C. et al., A Review of the Pathways of Human Exposure to Poly- and Perfluoroalkyl Substances (PFASs) and Present Understanding of Health Effects. J; OF EXPOSURE SCI. & ENV'T EPIDEMIOLOGY (Nov. 23, 2018), https://rdcu.be/dcPnE.] EPA needs to address this regrettable substitution problem by moving expeditiously to incorporate additional PFAS chemicals into federal drinking water standards and regulating the discharge of all PFAS chemicals.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Washington County Department of Public Health and Environment (Doc. #1739, SBC-043574)

Total PFAS MCL

In line with the MPCA, the county encourages EPA to consider development of a total (summed) PFAS MCL or similar type of regulatory value to account for exposures to PFAS in drinking water that do not have MCLs (and are unlikely to any time soon).

• A summed PFAS MCL would incorporate the detected concentrations of several PFAS, to be selected by EPA – possibly 10 or 20 of the most commonly detected PFAS chemicals that do not currently have risk evaluations, and provide guidance in situations where multiple PFAS are present in drinking water at concerning levels yet there is no MCL to evaluate the threat to human health.

• As an example, the European Union (EU) 2020 drinking water directive (DWD) includes drinking water standards for a defined sum of 20 PFAS at 100 ng/L or for a total PFAS at 500 ng/L.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document. The EPA notes that its research program is actively investigating many areas where better scientific or technical information is necessary prior to considering whether to develop a total PFAS regulation.

Arizona Water Company (Doc. #1758, SBC-044540)

PFAS Regulation and the Maximum Contaminant Level

In the EPA's Federal Register, Volume 88, No. 60, published Wednesday, March 29, 2023, the EPA stated "Depending on the individual PFAS, health effects can include negative impacts" on physical health. The current preliminary regulatory determination only regulates six PFAS contaminants. There are more than six PFAS present in drinking water (including, but not limited to, the 29 additional PFAS being monitored via UCMR 5). The Company recommends the EPA conduct further research into the regulation of PFAS contaminants prior to implementing or adjusting Maximum Contaminant Levels ("MCL").

Conclusion

The Company values the EPA's willingness to accept public comment on the proposed PFAS rule. Implementation of the proposed rule impacts public and private water utilities. As a private water utility, the Company would like to thank the EPA in advance for reviewing our comments and taking them into consideration.

Andrew J. Haas

Vice President - Engineering

PFAS Regulatory Coalition (Doc. #1761, SBC-046072)

3. The Coalition has concerns about the potential for expanded use of the Hazard Index approach.

The Coalition is concerned that use of the HI approach could be expanded. As discussed above, the Coalition doubts the validity of an HI as meeting the definition of an MCL, and the Coalition is opposed to use of the HI as presented in the Proposal, which adds across different modes of

action - especially for compounds where the co-occurrence conclusion is not justified by the data. These concerns are made even stronger when EPA states that "additional PFAS can be added over time once more information on health effects, analytics, exposure, and/or treatment becomes available, and merits additional regulation as determined by EPA." 88 Fed. Reg. 18670. EPA also says that "this approach provides a framework for Federal and State agencies to consider using to address PFAS in the future as needed." Id. The Coalition does not agree that the framework presented is appropriate for adding compounds over time or for other agencies to consider using.

EPA also does not make clear how, if at all, it would update the HI if there are updates to the science. The HI is based on HBWCs for each of the individual compounds. If there is an update needed to one or more of the HBWCs, would EPA update the HI through a future rulemaking? The current HI approach relies on HBWCs that are a combination of previously published Health Advisory Levels (for GenX and PfBS) and HBWCs that were separately developed as part of the MCL derivation (for PFNA and PfHxS). None of these is a regulatory value. The HBWCs for PFNA and PfHxS are even more uncertain: EPA acknowledges that there is no published EPA toxicity assessment for either of these chemicals, offering only that these assessments are under development and expected to undergo external peer review sometime in 2023. What happens to the HI if peer-review results in recommendations changes to these values? EPA has made dramatic swings in how it approaches PFOA and PFOS (see, e.g., the discussion in Section B, supra), so it would not be surprising if similar changes in EPA's approach were to occur with the other PFAS compounds as the science develops.

Similarly, if EPA wants additional PFAS compounds to be subject to an HI in the drinking water standards, would the Agency add them to those already included in the proposed HI, or would EPA create a new group with an additional HI? Again, as EPA has provided no sound basis for why it is combining these four PFAS compounds in a HI , the Coalition cannot meaningfully comment on that proposal. The Proposal also does not explain the basis EPA would use to update the HBWCs and how EPA would choose whether and which additional PFAS to include in this HI or a new HI, again depriving the Coalition of notice of EPA's regulatory approach and the opportunity to comment on it.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Silent Spring Institute (Doc. #1784, SBC-045805)

Considerations for future drinking water regulations

The proposed standards should be finalized without delay. Here we add supplementary comments for EPA to consider implementing after these PFAS standards have been finalized.

There is ample evidence that MCLs ought to be considered for PFDA (C10), PFUnDA (C11), and PFDoDA (C12). The health effects and toxicokinetic behavior of the C10-C12 compounds

show similarities to the behavior of PFNA, and the human half-lives for perfluorocarboxylates generally increase with chain length. Geometric mean human half-life for PFUnDA was 7.4 years, more than twice the estimated half-life for PFNA, which itself has concerning persistence.[REF33: Zhang YF, Beesoon S, Zhu LY, Martin JW. Biomonitoring of perfluoroalkyl acids in human urine and estimates of biological half-life. Environ Sci Technol. 2013;47(18):10619-10627.] As noted in the ATSDR Toxicological Profile, PFDA, PFUnDA, and PFDoDA have been associated with thyroid disorders and adverse birth outcomes in epidemiological studies.22 The ATSDR Toxicological Profile also shows that PFDA and PFUnDA have been linked with serum lipid outcomes, neurodevelopmental outcomes, and prostate cancer. PFUnDA and PFDoDA have been linked to suppressed antibody response to vaccines and decreases in childhood growth. PFDA has been linked with male reproductive outcomes and adverse pregnancy outcomes, and PFUnDA has been linked to diabetes. Mother-child transfer efficiencies for these compounds can be even greater than PFNA, as indicated by the low maternal-fetal and maternal- infant ratios reported in the ATSDR toxicological profile.

EPA should also consider incorporating a total PFAS and precursor assay as part of regular screening to address a wider set of PFAS chemicals than six alone. A one-by-one approach to regulating PFAS would be inefficient given the number of possible PFAS. EPA's own PFAS Master List contains over 12,000 possible PFAS compounds. Although this recommendation may be beyond the scope of the Safe Drinking Water Act, EPA should consider this option as part of the routine source water quality monitoring under the Groundwater Monitoring Rule, Surface Water Treatment Rule, or other applicable source water regulations.

A total PFAS and precursor assay test would better estimate and monitor the full extent of PFAS contamination. There are many other highly prevalent PFAS not covered by the rule. A 2016 study found that over 16 million U.S. residents were served by public water systems with detectable PFAS concentrations in the 2013-2015 UCMR3 cycle.[REF4: Hu XC, Andrews D, Lindstrom AB, et al. Detection of poly- and perfluoroalkyl substances (PFASs) in U.S. drinking water linked to industrial sites, military fire training areas and wastewater treatment plants. Environ Sci Technol Lett. 2016;3(10):344-350.] However, the UCMR3 underestimated the full extent of PFAS in public drinking water supplies, because the reporting limits ranged from 10 to 90 ng/L. These limits were well above concentrations that could be measured by analytical laboratories and above health guidelines established by some state health departments. A reanalysis by Eurofins Eaton Analytical of the UCMR3 samples concluded that, based on a reporting limit of 5 ng/L, nearly 30% of public water supplies likely contained at least one PFAS chemical above this level.[REF34: Eaton A. A Further Examination of a Subset of UCMR 3 PFAS Data Demonstrates Wider Occurrence. http://greensciencepolicy.org/wp-content/uploads/2017/12/Andy_Eaton_UCMR3_PFAS_data.pdf. Published 2017. Accessed 20 June 2018.] The Environmental Working Group extended this analysis and estimated that 110 million Americans may have > 5 ng/L PFAS in their drinking water.[REF35: Environmental Working Group. Report: Up to 110 Million Americans Could Have PFAS-Contaminated Drinking Water. 2018.] Another Environmental Working Group report found PFOA and PFOS in 43 out of 44 public water systems tested.[REF36: Environmental Working Group. PFAS

Contamination of Drinking Water Far More Prevalent Than Previously Reported. Washington, DC, 2020.] In addition, a 2018 study by the EPA and U.S. Geological Survey of 25 public water systems found PFOA in 100% and PFOS in 92% of treated water samples. Seven other PFAS compounds (PFBS, PFHxS, PFBA, PFPeA, PFHxA, PFHpA, and PFDA) were detected in at least 80% of treated water samples.

Finally, we recommend that EPA consider the rule's long-term commitment to addressing PFAS in drinking water. It will be important for EPA's PFAS drinking water standards to be responsive to a rapidly evolving scientific landscape. Currently, the proposed rule is unclear about how EPA will address emerging hazard data. EPA should articulate an efficient mechanism to incorporate PFAS that meet regulatory criteria into the hazard index or as a standalone MCL. There may be a need to add language that clarifies under what conditions should PFHxS, HFPO-DA, PFNA, and PFBS be removed from the hazard index and regulated as a standalone MCL like PFOA and PFOS. In the event that new evidence indicates a similar toxicological mode of action across multiple PFAS or a significant toxicological effect from PFAS mixtures, which is a current national research priority, it is unclear if EPA will adjust its grouping approach. All of this underscores the likely need for EPA to respond quickly to new toxicological data as they emerge.

Thank you for this opportunity to comment. Please contact us if you wish to discuss any of the above further.

PFAS Project Lab (Doc. #1786, SBC-044720)

In conclusion, we emphasize the importance of adopting the proposed drinking water standards without delay given EPA's obligation to protect human health and the environment. We see this as the first step in addressing a long overdue lack of regulatory oversight over these chemicals of significant health concern. Given the number of PFAS in commerce (and the dozens of new PFAS awaiting EPA approval), EPA cannot fully protect public health and the environment until pursuing broader class-based action following the adoption of this proposed rule. Following this, we encourage separate rulemaking that takes a more comprehensive class-based approach to addressing additional PFAS not covered by EPA's proposal, yet found frequently in environmental media such as drinking water; EPA can look towards the European Union's work to establish a drinking water standard for "the totality of per- and polyfluoroalkyl substances" for guidance (E.U. 2022).

Respectfully,

Dr. Alissa Cordner, Associate Professor of Sociology, Whitman College, co-director of the PFAS Project Lab

Dr. Phil Brown, University Distinguished Professor of Sociology and Health Sciences, Northeastern University, co-director of the PFAS Project Lab

Dr. Jennifer Liss Ohayon, Affiliate Researcher at Northeastern University and member of the PFAS Project Lab

Mindi Messmer (Doc. #1788, SBC-044709)

4. Please regulate these chemicals as a class. We are tired of playing whack-a-mole with the manufacturers who slightly modify the chemical structure to stay ahead of health studies.

5. Regulating PFAS chemicals as a group would also stop the use of precursors that readily convert to legacy PFAS chemicals. End the corporate welfare system that allows corporations to poison us for profit.

Thank you for your attention to this matter.

Mindi Messmer, MS, PG, CG Rye, NH

Mark Gearreald (Doc. #1792, SBC-044297)

3. Please regulate these chemicals as a class. We are tired of playing whack-a-mole with the manufacturers who slightly modify the chemical structure to stay ahead of health studies.

4. Regulating PFAS chemicals as a group would also stop the use of precursors that readily convert to legacy PFAS chemicals.

Thank you for your attention to this matter.

Sincerely,

Mark S. Gearreald

James McConnell mcc988@icloud.com 42 Monadnock Highway

North Swanzey, New Hampshire 03431

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Peggy Kurtz (Doc. #1799, SBC-046045)

Ultimately, PFAS must be regulated as a class. This is the only way to control the ongoing pollution.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Massachusetts Municipal Association (MMA) (Doc. #1800, SBC-043762)

The four other PFAS chemicals – perfluorononanoic acid (PFNA), hexafluoropropylene oxide dimer acid (HFPO-DA, commonly known as GenX Chemicals), perfluorohexane sulfonic acid (PFHxS), and perfluorobutane sulfonic acid (PFBS) – would be regulated as a mixture of chemicals through a hazard index (HI) calculation. Under the proposal, a running annual average hazard index value greater than 1.0 would be a violation of the proposed HI MCL. Two PFAS chemicals with a regulatory history in Massachusetts, PFHpA and PFDA, are left untouched by this NPDWR proposal.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

National Ground Water Association (NGWA) (Doc. #1804, SBC-045470)

[The steps identified in that letter include:]

• engaging experts to develop a public health risk assessment for PFAS beyond PFOA and PFOS to guide determining which PFAS or groups of PFAS should be targeted for future action,

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Earthjustice et al. (Doc. #1808, SBC-046096)

In a separate rulemaking, EPA should establish drinking water standards for the PFAS that are not covered by EPA's current proposal, including class-based standards that address the harms from additional PFAS mixtures. We urge EPA to use the full extent of its SDWA authority to ensure that no one suffers the harms associated with PFAS-contaminated drinking water.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Earthjustice et al. (Doc. #1808, SBC-046099)

B. EPA Should Pursue Additional, Class-Based PFAS Drinking Water Standards

While EPA's proposal marks an important step towards addressing the PFAS crisis, further action is needed to protect communities who are exposed to additional PFAS in their drinking water. A recent peer-reviewed, published study of tap water collected from 16 states, including more than 20 samples from public water supplies, detected 26 different PFAS, only six of which are covered by EPA's proposed rule. [FN19: Katherine E. Pelch et al., 70 Analyte PFAS Test Method

Highlights Need for Expanded Testing of PFAS in Drinking Water, 876 Sci. of the Total Env't Art. No.162978 (2023), https://www.sciencedirect.com/science/article/pii/S0048969723015966.] Another study of U.S. surface waters found 35 PFAS across 29 states and the District of Columbia, with one or more PFAS detected in 83% of the water bodies sampled. [FN20: Waterkeeper All., Invisible, Unbreakable, Unnatural: PFAS Contamination of U.S. Surface Waters, at 13 (Oct. 2022), https://waterkeeper.org/wp-content/uploads/2022/10/Waterkeeper-Alliance-PFAS-Report-FINAL-10.14.22.pdf.] Many of the PFAS detected but not covered by EPA's proposal, such as perfluorobutanoic acid ("PFBA") and perfluoroheptanoic acid ("PFHpA"), are associated with an increased risk of thyroid toxicity, liver damage, and developmental impairment, exacerbating the harms from the PFAS that are subject to EPA's proposed standards. [FN21: EPA, IRIS Toxicological Review of Perfluorobutanoic Acid (PFBA, CASRN 375- 22-4) and Related Salts, at 4-1–4-2 (Dec. 2022), https://www.epa.gov/system/files/documents/2022- 12/10945-%20PFBA%20ToxReview%20Final%20December%202022-HERO_partial-508%20%28updated%20page%20100%29.pdf; Health and Env't All., The Curious Case of PFHpA and Why This and All Forever Chemicals Should be Banned Under REACH (Dec. 13 2022), https://www.env-health.org/the-curious-case-of-pfhpa-and-why-this-and-all-forever-chemicals-should-be-banned-under-reach/.] Notably, PFBA, perfluorohexanoic acid ("PFHxA"), and perfluorodecanoic acid ("PFDA"), all have finalized or draft toxicity assessments performed by EPA's Integrated Risk Information System ("IRIS"). [FN22: EPA, IRIS Toxicological Review of Perfluorobutanoic Acid; EPA, IRIS Toxicological Review of Perfluorohexanoic Acid [PFHxA, CASRN 307-24-4] and Related Salts (Apr. 2023), https://cfpub.epa.gov/ncea/iris/iris_documents/documents/toxreviews/0704tr.pdf; EPA, IRIS Toxicological Review of Perfluorodecanoic Acid [PFDA, CASRN 335-76-2] and Related Salts (Public Comment and External Review Draft) (Apr. 2023), https://ordspub.epa.gov/ords/eims/eimscomm.getfile?p_download_id=546623.]

Like GenX, PFBS, PFNA, and PFHxS (collectively, the "Hazard Index PFAS" or "HI PFAS"), these other detected PFAS also meet the three statutory criteria for regulation under the SDWA. [FN23: See 42 U.S.C. § 300g-1(b)(1)(A) (requiring EPA to develop MCLGs and national primary drinking water regulations for contaminants that EPA determines "may have an adverse effect on the health of persons," are known or substantially likely to occur in public water systems "with a frequency and at levels of public health concern," and present "a meaningful opportunity for health risk reduction for persons served by public water systems").] EPA has found that PFBA, PFHxA, and PFDA "may have an adverse effect on the health of persons," [FN24: Id. § 300g-1(b)(1)(A)(i).] and that they are associated with many of the same health effects observed following exposure to other PFAS, as summarized in Table 1 below. There are sufficient occurrence data from state monitoring efforts to support the need to protect against exposure to these PFAS in drinking water. [FN25: See id. § 300g-1(b)(1)(A)(ii).] Regulation of these PFAS in drinking water, individually and as a mixture with other PFAS, "presents a meaningful opportunity for health risk reduction for persons served by public water systems." [FN26: Id. § 300g-1(b)(1)(A)(iii).]

[FN27: EPA, IRIS Toxicological Review of Perfluorobutanoic Acid, at xiii (Table ES-1. Evidence integration judgements and derived toxicity values for PFBA). FN28: Organ/system-specific oral reference dose. FN29: EPA, IRIS Toxicological Review of Perfluorohexanoic Acid [PFHxA, CASRN 307-24-4] and Related Salts, at xv (Apr. 2023). FN30: EPA, IRIS Toxicological Review of Perfluorodecanoic Acid (PFDA) and Related Salts (Public Comment and External Review Draft, at xvii-xviii (Apr. 2023).]

Health effects in bold were selected by EPA as the chronic or lifetime RfD.

Moreover, with more than 1,000 PFAS already in commerce and dozens of new PFAS awaiting EPA approval, EPA cannot fully protect public health or the environment by regulating individual PFAS (or even small sub-groups of PFAS) one at a time. Separate from its Proposed Rule, EPA should pursue a broader, class-based PFAS drinking water standard. Leading scientists have called for class-based standards [FN31: Carol F. Kwiatkowski et al., Scientific Basis for Managing PFAS as a Chemical Class, 7 Env't Sci. & Tech. Letters 532, 532–43 (2022), https://pubs.acs.org/doi/10.1021/acs.estlett.0c00255.] and the European Union has established a drinking water standard, which will take effect in January 2026, for "the totality of per- and polyfluoroalkyl substances." [FN32: Directive 2020/2184 of the European Parliament and of the Council of the European Parliament and of the Council of 16 December 2020 on the Quality of Water Intended for Human Consumption, 2020 O.J. (L 435), https://eur-lex.europa.eu/legal-content/EN/TXT/HTML/?uri=CELEX:32020L2184; see also Health Canada, Draft Objective for Per- and Polyfluoroalkyl Substances in Canadian Drinking Water: Rationale, https://www.canada.ca/en/health-canada/programs/consultation-draft-objective-per-polyfluoroalkyl-substances-canadian-drinking-water/rationale.html (last updated Feb. 10, 2023) (proposing 30 ppt drinking water limit for "total PFAS in drinking water," using detection methods capable of measuring at least 18 PFAS).] Similarly, the Canadian government recently found that "a precautionary, class-based approach to addressing PFAS is needed to protect the environment and people from anticipated adverse effects." [FN33: Environment and Climate Change Canada and Health Canada, Draft State of Per- and Polyfluoroalkyl Substances (PFAS) Report at 113-114 (May 2023), https://www.canada.ca/content/dam/eccc/documents/pdf/pded/pfas/draft-state-pfas-report.pdf.] "Addressing PFAS as a class of chemicals would also reduce the chance of regrettable substitution," or the replacement of PFAS that regulated under the SDWA with equally toxic but less studied PFAS that are not subject to SDWA controls. [FN34: Id. at 116.]

The SDWA does not require detailed information about every member of the class to protect the public from their cumulative health effects. EPA previously established a class-based drinking water limit for polychlorinated biphenyls ("PCBs") despite acknowledging that "the toxicity of [the 209 possible PCB isomers] has not been fully characterized. [FN35: National Primary Drinking Water Regulations—Synthetic Organic Chemicals and Inorganic Chemicals; Monitoring for Unregulated Contaminants; National Primary Drinking Water Regulations Implementation; National Secondary Drinking Water Regulations, 56 Fed. Reg. 3,526, 3,546

(Jan. 30, 1991).] Here, too, the presence of multiple PFAS in the same drinking water supplies, as well as those chemicals' shared persistence and potential for common health effects, supports a class-based MCL. In addition to finalizing the Proposed Rule to protect communities with PFOA, PFOS, and the HI PFAS in their drinking water, EPA should also pursue a separate rulemaking process, beginning with a class-based PFAS regulatory determination, to establish drinking water standards that cover all mixtures of PFAS in drinking water.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Clean Water Action (Doc. #1813, SBC-045497)

Thousands of PFAS chemicals are in use and many are found in mixtures in water around the country. EPA should address the whole class of PFAS chemicals wherever possible.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Clean Water Action (Doc. #1852, SBC-045501)

Thousands of PFAS chemicals are in use and many are found in mixtures in water around the country. EPA should address the whole class of PFAS chemicals wherever possible.

Sincerely,

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

National PFAS Contamination Coalition (Doc. #1830, SBC-044553)

However, this should be viewed as a first step. With over 11,000 of these chemicals in the PFAS class, we do not believe in a chemical by chemical approach. To adequately protect our communities, ultimately we will need to regulate these chemicals as a class. We also know that there is no safe level of PFAS in our drinking water. We have seen current technology with detection ability as low as 2 ppt, thus we would urge the EPA to implement a best-available technology based standard that would be lowered to 2 ppt and would continue to lower as detection technology improves.

We urge the EPA to act quickly and decisively in establishing new MCLs for PFAS. We cannot afford to wait any longer to address this critical issue. Thank you for your attention to this matter.

Sincerely,

The National PFAS Contamination Coalition

Douglas Whitbeck (Doc. #1853, SBC-045504)

3. Please regulate these chemicals as a class. We are tired of playing whack-a-mole with the manufacturers who slightly modify the chemical structure to stay ahead of health studies.

4. Regulating PFAS chemicals as a group would also stop the use of precursors that readily convert to legacy PFAS chemicals.

Thank you for your attention to this matter. Our water is really all connected.

Great Lakes PFAS Action Network (Doc. #1870, SBC-045872)

These proposed regulations are long overdue and we fully support this first step of regulating six dangerous PFAS in drinking water. In addition, we encourage the EPA to take a comprehensive approach to regulating the entire class of chemicals in order to reduce overall PFAS exposure, and improve drinking water safety in thousands of communities across the country.

Thank you for your consideration.

[Table 1: See Docket ID EPA-HQ-OW-2022-0114-1870]

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Eri Higashi Durnell (Doc. #2048, SBC-047629)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Judith Moriarty (Doc. #2049, SBC-047637)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

The EPA MUST act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

I hope you will take my concerns, as well as those of thousands of others, seriously for even you might, someday, look back and appreciate the wisdom of protection a resource more valuable than any other for life itself.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Dorie Reisenweber (Doc. #2050, SBC-047587)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act posthaste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. BAN them. That is the only way to stop these forever toxins. Stop the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, END, not limit, pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

Remember these forever chemicals don't go away. Don't be like some ignorant politicians who discuss PFAs cleanup. If and when that is possible and affordable on mass scale, massive harm will have already been done. Limiting is a baby step. The health problems won't end until we BAN the production of PFAS and like chemicals. I urge the EPA to take that bold step and BAN PFAS and similar chemicals.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Chris Rauber (Doc. #2051, SBC-047607)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Edward Hyman (Doc. #2052, SBC-047659)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well established, as they are documented in dozens of human health studies, as well as in hundreds of experimental animal studies. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. This is an important "real life" model, since human bodies ingest, integrates and digests them all simultaneously . EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products.

EPA must cease approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, and limit pollution caused by biosolids/sludge fertilizers.

Further, it is of utmost importance that the EPA establish health-based limits for PFAS in subsistence fish and other wild foods ingested directly or indirectly by human beings.

EPA's adoption of these policies will begin to recognize our current understanding of the necessary inherent re-examination of various chemicals only viewed previously in isolation, yet which interact and affect the human species not independently, but with synergistic and interactive effects. Recognizing these interactive elements of the chemicals allows for more correct modeling of the impact on human subjects.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Cinda Flynn (Doc. #2053, SBC-047651)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the

potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Anthony Gatenby (Doc. #2054, SBC-047666)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

With the wide range of pollutants commonly reported in manure biosolids, the potential risks associated with long-term land application operations are concerning. In a recent study, PFAS in surface soils, deeper soils into the vadose zone, and immediately-underlying groundwater was measured at an agricultural station with a long record of biosolids applications. Twelve PFAS homologous were detected in every near surface soil sampled 030 cm depth below ground surface with multiple PFAS (especially short-chain) distributed through the soil profile.

Measured concentrations of PFAS in the soil profile (090 cm) show that these compounds have migrated to deeper soil depths (up to 9 m below the surface) with quantifiable concentrations in the soil and the immediate underlying groundwater located approximately 17 m below. Researchers across the globe have reported PFAS and related compounds in groundwater and soils following the application of PFAS-containing soil amendments including manure biosolids and compost (https://www.sciencedirect.com/science/article/abs/pii/S004313542101229Xvia%3Dihub).

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Lorene A (Doc. #2055, SBC-047593)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Andrea Thompson (Doc. #2056, SBC-047574)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Frederick Ellsworth (Doc. #2068, SBC-047518)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS

chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Tonda Bian (Doc. #2069, SBC-047550)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Jenny Walker (Doc. #2070, SBC-047564)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods is beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Elsa Obuchowski (Doc. #2071, SBC-047532)

The hazards of PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are documented by many studies with both humans and animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to strong regulation of PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Most important in my opinion, EPA needs to address ASAP the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval

of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods is beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Samantha Corte (Doc. #2073, SBC-047548)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Dawna Hammers (Doc. #2075, SBC-047526)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Charles Adelman (Doc. #2076, SBC-047576)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS

chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

N L (Doc. #2077, SBC-047645)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Katherine Weaver (Doc. #2078, SBC-047524)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. Perry Cogburn (Doc. #2099, SBC-047609)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Judith Allen-Leventhal (Doc. #2100, SBC-047558)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has

published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Donna Thomas (Doc. #2101, SBC-047662)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

We are counting on our EPA Reg 6.

I strongly support the proposed drinking water limits EPA has proposed for six PFAS chemicals. Due to the slow pace of regulatory agencies, many Americans have been drinking harmful amounts of PFAS chemicals for decades. These rules will speed the implementation of life-saving water treatment for communities across the U.S. Therefore the Agency must finalize these rules as quickly as possible.

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Patrick Sharp (Doc. #2104, SBC-047568)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Rian Raby (Doc. #2105, SBC-047570)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Roland Hofman (Doc. #2106, SBC-047582)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Lara Levison (Doc. #2113, SBC-047639)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Aileen Curfman (Doc. #2115, SBC-047625)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Doris Cellarius (Doc. #2116, SBC-047520)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked releases of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, stop allowing dumping of PFAS waste into the wastewater system, and ban land application of biosolids and sewage effluent because they all have been found to contain PFAS.

To address widespread pollution of waters and foods EPA must set health-based limits for PFAS in foods, fish and wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Mary Bautista (Doc. #2118, SBC-047516)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals.

I also support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Donna Brown (Doc. #2124, SBC-047597)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA

response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Tracy Frisch (Doc. #2119, SBC-047417)

Chronic exposures to PFAS chemicals found in drinking water can cause severe health problems, especially in young children and developing fetuses. I strongly support the proposed drinking water limits EPA has proposed for six PFAS chemicals.

But regulating 6 PFAS, while an advance forward, is far from sufficient to protect public health. EPA needs to regulate PFAS as a chemical class, rather than trying to regulate individual PFAS chemicals.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Melissa Tomlinson (Doc. #2262, SBC-047633)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the

EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Leslie Bennett (Doc. #2282, SBC-047530)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Elizabeth Becker (Doc. #2288, SBC-047589)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the

potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Lori Olinger (Doc. #2334, SBC-047544)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the

potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Stephen Brown (Doc. #2335, SBC-047641)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the

EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

David Dow (Doc. #2336, SBC-047649)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Susan Johnson (Doc. #2398, SBC-047566)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the

potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Samantha Herdman (Doc. #2539, SBC-047461)

I am concerned, however, that EPA is only taking action to restrict, monitor and report six PFAS contaminants. There are more than 9,000 known PFAS chemicals, and at least 180 are considered toxic by the EPA because they are on the Toxic Release Inventory (CDC 2023; US EPA 2019). EPA acknowledges that PFAS act in a dose-additive manner, suggesting that combinations of the 9,000 PFAS may lead to health impacts generally associated with the class of chemicals, including cancer, negative impacts on fetal growth, development, reproduction, liver, thyroid, immune function, the nervous system and more. EPA should set class-based MCLGs or a Hazard Index score that encompasses all PFAS contaminants found in drinking water. Spending years studying the impacts of each individual PFAS contaminant will take decades, and in the mean-time the public will be at risk of exposure. A precautionary measure to protect the public health from PFAS contamination is justified by the available information about PFAS. Furthermore, restricting only some PFAS contaminants will likely lead to the adoption of other PFAS. This has already happened, when manufacturers replaced the well-studied PFOA and PFOS with alternative PFAS (EPA 2021a). Setting a class-based precautionary standard to regulate PFAS will be technologically difficult. However, the EPA already has access to technology to specifically identify at least 50 PFAS, according to the U.S. Government Accountability Office's technology assessment (2022).

I support EPA's proposal to set legally enforceable standards for six PFAS – but EPA should also do more. If those six PFAS are just replaced with similar, toxic replacements, the PFAS NPDWR will have a woefully inadequate result. EPA should set class-based restrictions to prevent Americans from drinking any dangerous PFAS contaminant.

Waterkeeper Alliance (Doc. #3072-2, SBC-046341)

My name is Kelly Hunter Foster, and I'm a senior attorney and Clean Water Defense campaign manager for the Waterkeeper Alliance. We strongly support the regulation of PFAS in drinking water, and we commend EPA for proposing protective, scientifically-supported standards for six PFAS, and for also recognizing that both individual PFAS and chemical mixtures of PFAS pose very serious threats to human health at low levels. Given the widespread dispersion of PFAS in the environment, and the seriousness of the health effects posed by these chemicals, the adoption of national drinking water standards is long overdue, and we urge EPA to act quickly to finalize these standards. Waterkeeper groups across the country are seeing PFAS contamination of

surface water and groundwater, including public water supply source waters, and are concerned about the impacts of PFAS pollution on their communities, both in terms of contaminated drinking water, and the urgent need for standards and funding for public utilities, to properly treat wastewater and drinking water, and to safely manage contaminated treatment residuals. For example, last year Waterkeeper groups conducted PFAS testing in 114 waterways in 34 states and the District of Columbia. 83 percent of the waterways tested were found to contain at least one, but often many, of the 35 PFAS chemicals that were detected. In some places, the level of contamination was thousands to hundreds of thousand times higher than what is believed to be safe for drinking water. Unexpectedly, many lesser-known PFAS chemicals were detected with high frequency. For example, testing found PFHxA in 153 samples, PFPeA in 126 samples, and there are a lot of other examples of that. Multiple PFAS chemicals were detected in the majority of individual water samples, adding to the total concentration of PFAS in the waterways, and increasing the risk of harm. For example, a waterway in Pennsylvania was contaminated by 27 different PFAS chemicals and had a total concentration of 6,510.3 parts per trillion. This is one of the reasons that we support EPA's proposal to use a hazard index to address co-occurring PFAS that, like many other members of the PFAS class, have similar structures and present similar risks. Thank you for the opportunity to provide these comments to you today.

EPA Response: The commenter supports using the Hazard Index to regulate co-occurring PFAS. Please see sections 4.3.5 and 4.3.2 of the EPA response in this *Response to Comments* document.

Karin Hemmingsen (Doc. #2617, SBC-047601)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Vermont PFAS/Military Poisons Coalition (Doc. #2715, SBC-047305)

I am the Coordinator of the VT PFAS/Military Poisons Coalition. Our Coalition believes that the EPA's proposed drinking water standards, while a step forward, are not comprehensive enough, take too long to enact, and don't set PFOA and PFOS at the limits needed to protect people and animals from harm. The EPA's chemical by chemical approach is not good enough to protect public health and the environment. We must regulate PFAS as a class of chemicals, and ban all but absolutely essential uses of these toxins and allow no new PFAS to enter the market.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Allison Nemenyi Shiozaki (Doc. #2739, SBC-047635)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids

management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Mary Matz (Doc. #2787, SBC-047617)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. In regard to discussion related to the Hazard Index, please see section 4.3.2 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Kevin Rolfes (Doc. #2802, SBC-047439)

For PFOA and PFOS, whose carcinogenic nature requires setting their Maximum Contaminant Level Goal at 0.0 parts per thousand (PPT), the proposed Maximum Contaminant Level (MCL) allowed in drinking water of 4 PPT is adequate to protect public health, reasonable, and feasible for both testing and treatment. PFHxS, HFPO-DA, PFNA, and PFBS have not been classified as carcinogens, but have been shown to affect health in a cumulative, additive manner. They often exist as mixtures in water, as found in the Pennsylvania drinking water sampling study where, for example, approximately 70% of samples containing PFNA also contained at least one other

PFAS species that is not PFOA or PFOS. EPA effectively addresses this issue of "dose additivity" by setting a Health Based Water Concentration (HBWC) value for the level of each chemical, and a Hazard Index (HI) for the mix. The proposed values are adequate to protect health, reasonable, and achievable.

To maintain the efficacy of the proposed rule, I ask that EPA continue reviewing data regarding the health effects of these compounds, adjusting the MCLs and HBWC values and adding more chemicals to the regulations as new data becomes available.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Therese Argoud (Doc. #2808, SBC-047591)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. In regard to discussion related to the Hazard Index, please see section 4.3.2 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Louis Pisha (Doc. #2891, SBC-047619)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

Finally, PFAS should be regulated as a class. Spending time going chemical by chemical when the industry is quickly coming up with replacements means we'll never stop being exposed.

Thank you fro considering my opinion in this proceeding.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. In regard to discussion related to the Hazard Index, please see section 4.3.2 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Michael Parietti (Doc. #2892, SBC-047631)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA’s expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the

potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. In regard to discussion related to the Hazard Index, please see section 4.3.2 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods is beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Keith Lewison (Doc. #2902, SBC-047655)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. In regard to discussion related to the Hazard Index, please see section 4.3.2 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild

foods is beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Gregory Grant (Doc. #2976, SBC-047668)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. In regard to discussion related to the Hazard

Index, please see section 4.3.2 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods is beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

John Lovie (Doc. #3060, SBC-046330)

EPA is proposing to use a Hazard Index (HI) approach to protecting public health from mixtures of PFHxS, HFPO-DA and its ammonium salt, PFNA, and PFBS because of their known and additive toxic effects and occurrence and likely co-occurrence in drinking water. Please consider drafting legislation and subsequent rulemaking around the criteria used to select and determine HBWCs for these compounds, rather than around the specific compounds meeting the criteria at the time. This way, other compounds meeting the criteria can be added without requiring modification of the legislation or rule.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document. Drafting legislation and potential future regulatory action to address additional PFAS is beyond the scope of this rulemaking action.

Mass comment campaign submitted by Naia Mitchell (Doc. #3065, SBC-047674)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. Next EPA should act with haste to address the unchecked emissions of these and other PFAS chemicals from industrial sites and consumer products. It must halt the approval of new PFAS chemicals, restrict dumping of PFAS waste into the wastewater system, limit pollution caused by biosolids/sludge fertilizers, and set health-based limits for PFAS in subsistence fish and other wild foods.

EPA Response: The EPA acknowledges the commenters' support for this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document. In regard to

discussion related to the Hazard Index, please see section 4.3.2 of the EPA response in this *Response to Comments* document. PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

Citizens Campaign for the Environment (Doc. #3072-64, SBC-047395)

The proposed EPA regulations are a great first step and should be implemented as quickly as possible to protect public health. However, there are thousands of PFAS chemicals with similar characteristics and health impacts. This should only be the start for EPA and the Agency should ultimately move to regulate PFAS as a class. Thank you again for the opportunity to comment.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Merrimack Citizens for Clean Water (Doc. #3072-68, SBC-047397)

I would urge you also to look at the chemicals that you're considering adding to CERCLA: PFBA, PFHxA, PFPeA, PFHpA, etc. You know the ones I'm talking about. Those are breaking through the GAC systems that we are currently paying for, immense amounts of money, and we really need the remediation to get this right. We can't wait, we don't have time here any longer. We have sick people and I would really love to see prevention for people across the country who do not know that they're being exposed as we didn't know for 20 years. Thank you so much.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

National Center for Health Research (Doc. #3072-73, SBC-047401)

Number two, we understand the Agency's desire to be flexible, but flexibility to satisfy monitoring requirements will likely generate a huge loophole. We ask EPA to have more explicit limits to prevent a weakening of these regulations. Number three, this proposed rule is an important first step, but it's long past time for EPA to define PFAS broadly, regulate them as a class and ban all non-essential uses.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Edith Couchman (Doc. #2083, SBC-047513)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has

published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. Clean Hall River Grassroots Advocacy Group (Doc. #3072-96, SBC-047408)

This has forced me to leave my town, sell my home, and purchase a home with a well. While I strongly support the EPA in their efforts, they are far too late for my family and fall short for my community. When we have way more than six PFAS coming downstream any given day. These six MCLs will not provide my town with what it needs. We need the entire PFAS class banned. There are over 9,000 individual chemicals in the PFAS family alone. And at this rate on a chemical-by-chemical basis, it would take the EPA 1,800 years to evaluate them for regulation at a five chemical per year rule. I urge you to use your powers, stand strong against chemical manufacturers who have demonstrated how pervasive their chemicals are, act swiftly with no delays, hold them accountable and make them pay for this cleanup. We're already sick and now have been dealing with water rate increases because of their lying by omission. My daughters, London and Berlin Bryant, ask you to show them the way and to battle for them. Thank you.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Paul Fishman and Mike Kurokawa (Doc. #2057, SBC-047538)

The hazards posed by PFOS, PFOA, HFPO-DA, PFBS, PFHxS and PFNA are well documented by dozens of human health studies and hundreds of experimental studies in animals. EPA has

published an exhaustive analysis of the potency of these six chemicals, as well as a detailed analysis of the economic benefits that will be realized by water limits.

In addition to the strong standards EPA is proposing for PFOS and PFOA, I support EPA's expedited action on the four chemicals it regulates with a hazard index approach. This method allows water managers to account for the additive impacts of exposure to multiple PFAS chemicals. EPA should extend this approach to include other PFAS chemicals when toxicological potency values are available, and consider ways that a hazard index can also account for the potential additive impacts of the hundreds of other PFAS chemicals found in water supplies for which health information is more scarce.

PFAS wastewater limits, biosolids management, and limits for subsistence fish and other wild foods are beyond the scope of this rulemaking. For a description of numerous current EPA activities related to PFAS, please see the EPA PFAS Strategic Roadmap (https://www.epa.gov/pfas/pfas-strategic-roadmap-epas-commitments-action-2021-2024).

CleanEarth4Kids.org (Doc. #3072-44, SBC-046367)

Thank you. Good afternoon. My name is Suzanne Hume. I'm the educational director and founder of CleanEarth4Kids.org. CleanEarth4Kids.org supports the EPA's proposed PFAS National Primary Drinking Water Regulations for PFAS forever chemicals. But this rule only establishes criteria for six PFAS found in drinking water. PFAS must be banned and regulated as a class with the most stringent levels of protection for clean, safe water, for children's health, public health, fish, birds, wildlife, and entire ecosystems. As we speak, PFAS forever chemicals are entering our water. PFAS forever chemicals known to harm children's health and future. PFAS not only disrupt lipid and amino acid metabolism, but alter thyroid hormone function in children. An altered thyroid can fail to process proteins and fats, affecting every cell in the body. Long-term effects of PFAS in children include developmental issues in the brain and lifelong high blood pressure. Furthermore, PFAS in pregnant women can cause liver failure in infants, underweight newborns, failed vaccine response, and early onset, kidney cancer and on and on and on. Increased cancer, preeclampsia during pregnancy. So much, too many to mention in this very short time. So, it is very important that we ban PFAS as a class and use the most stringent regulations possible. PFAS forever chemicals will remain in the environment for thousands of years and continue to harm children, pregnant women, seniors and the public, our fish, wildlife and ecosystems. The EPA has responsibility to defend our environment and protect public health. So, it's vital to ban PFAS as a class. Scientists from all the world using numerous studies showing that managing PFAS as a class is the most effective approach to reducing the adverse effect on human and ecological health. And 67 scientists requested that EPA implement this ban as a class stating it would provide an orderly and expeditious process. And California DTSC determined regulation of individual PFAS is ineffective and California already regulates PFAS as a class and certain bills that can be found on our website. PFAS are contaminants that have been detected in drinking water throughout the U.S. and the cost of not banning PFAS as a class and the most stringent standards is criminal. A cost to our children, families, not to mention taxpayers, we should not have to bear. You know, investigations, health reports, medical problems, increased bills, workplace productivity, diminished mental health, all of this is affected. When our fish are too contaminated to eat, come on, it's past time. Thank you so much from CleanEarth4Kids.

EPA Response: The commenter supports this PFOA, PFOS, PFHxS, PFNA, HFPO-DA, and PFBS rulemaking. In regard to regulating other PFAS, please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Cape Fear River Watch (Doc. #3072-47, SBC-046369)

Thank you. My name is Dana Sargent. I am the executive director of Cape Fear River Watch, a nonprofit team of five in Wilmington, North Carolina, dedicating ourselves to this issue since we found out our Cape Fear River, the drinking water for 500,000 people, was contaminated for more than 40 years by DuPont and then Chemours. In addition, we found through court-ordered well sampling, after our organization sued Chemours, that around 10,000 wells and counting are highly contaminated. Also, from that order, we learned that Chemours alone has been dumping more than 300 unique PFAS into our drinking water supplies. This doesn't include the high levels

of legacy chemicals. I want to thank you all for providing Q&A session and I hope you continue that trend. My Q&A discussion has informed my comments. I want to be clear, Cape Fear River Watch is grateful that EPA has finally gotten the ball rolling on regulating PFAS, since the industry's own scientists knew these chemicals were toxic 50 years ago. We also appreciate the recognition that we're exposed to mixtures, again, more than 300 in our water. To that end, this rule is missing a vitally important piece. There needs to be a mechanism for adding additional PFAS to this rule's Hazard Index component. During my private Q&A written convo, it was suggested that EPA is not considering this, but instead will be gathering information through 2025 through the UCMR process and wait until after that to potentially propose completely new regulation and start this long process all over again. And they mention that the filtration required for the six in this proposal will work to remove other PFAS that is simply not the case. In our water for instance, PFMOAA is of the highest concentration, and it breaks through GAC sooner than all others in our water. So, systems that are regulated to catch the larger PFAS in this proposal could allow PFMOAA to break through before the carbon is required to be cleaned, for lack of a better word. Waiting until 2025 for EPA to start the regulation process on another PFAS or set of PFAS is unethical and dangerous. It may not even occur depending on who's leading the EPA in 2025 and beyond. We simply cannot wait for a one at a time approach. Again, we ask that EPA include a mechanism for adding additional PFAS to this rule's Hazard Index. It will not only save EPA time and resources, it could save lives. Also relative to this regulation, we ask that EPA include clear guidance on filtration to ensure that, for instance, spent carbon is managed without PFAS emissions or discharge and transport of PFAS containing filtration components is safe. Aside from this regulation, we of course request EPA work quickly to hold polluters accountable rather than taxpayers and utilities. Thank you very much.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Michigan League of Conservation Voters (Doc. #3072-62, SBC-046378)

Hi. Thank you for providing the opportunity to comment on these critical drinking water protections. I applaud the EPA for proposing strong limits on six widely detected PFAS chemicals in our drinking water. My name is Shannon Ervin and I'm a resident of Michigan where I studied freshwater science and has since held positions related to monitoring and educating the public on water quality. It has been my responsibility to bring PFAS to the public's attention. Due to the commonalities of these chemicals, it is bizarre, however, how unknown they are to the general public, especially when they have such a broad spectrum of health impacts. It is a relief that the EPA will be issuing protections on the public's behalf. However, damage has already been done. In regard to these proposed limitations, I urge you to act quickly on the entire class of chemicals rather than one by one. With an approximate 200 million people drinking contaminated water supplies, this proposal would save thousands of lives and prevent tens of thousands of serious PFAS-related illnesses yearly. In my line of work, I hear stories of individuals experiencing health problems by unknowingly consuming PFAS or knowingly consuming PFAS and not having a choice as there is no polluter pay or enforceable cleanup to

the polluters. This has built a community of people who represent the impacted communities in the Great Lakes PFAS Action Network. These impacted community members have been exposed to both individual PFAS and chemical mixtures of PFAS, which is why they are encouraging that the EPA propose to use a hazardous index on GenX, PFBS, PFNA, and PFHxS to inform risk of chemical mixtures. These proposed regulations are long overdue and fully support this first step of regulating six dangerous PFAS chemicals in drinking water. As the EPA moves forward and considers additional standards and actions, it is very important to take a comprehensive approach to regulate the entire class of chemicals. Addressing the entire class of PFAS will reduce overall exposure and improve drinking water safety for thousands of communities across the country. And since... Oh, and I'm out of time, thank you so much.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.

Michigan League of Conservation Voters (Doc. #3072-79, SBC-046388)

Hello, my name is Lena Swirczek, and I am a regional organizer for the Michigan League of Conservation Voters in southeast Michigan. I want to start by thanking the EPA for holding this hearing about strong proposed drinking water standards for its six PFAS chemicals. I am a resident of Oak Park, Michigan and I live in the Rouge River Watershed. In recent years, there have been growing concerns about elevated PFAS levels, especially in fish. Although I don't know of any current issues with my drinking water, I'm also aware that the blood of nearly every person in the United States contains PFAS, including likely myself. Whether or not I have a current water advisory, this issue is extremely important to me and others in my community who cannot be on this call today. PFAS chemicals present an extreme danger to every person in Michigan and the rest of the United States. Exposure to PFAS could prevent me from having children, cause cancer, and even hurt my immune system, which is especially terrifying as we continue to live with COVID. My heart breaks for everyone that has already faced these health effects from PFAS, especially knowing that proper regulation could have prevented this suffering in the first place. I appreciate that the EPA is finding the science that shows that virtually no levels of PFAS chemicals are safe to drink. This new standard is an important first step in protecting the public. However, we also need the EPA to move towards regulating the entire class of PFAS chemicals rather than on a one-by-one basis. Companies like 3M and DuPont have known that PFAS chemicals as a whole pose serious health threats since the 1950s. That is older than both me and my parents. I don’t want to be a grandmother by the time we take serious action towards addressing all of the PFAS chemicals that contaminate our water, food, soil, and air. This issue is long overdue, and we need action from the EPA to act broadly and boldly to protect the public. Addressing PFAS as a class of chemicals would save thousands of lives and hopefully prevent future contamination. Thank you for proposing this important first step and I hope to see further action from the EPA on additional PFAS chemicals soon.

EPA Response: Please see section 4.3.5 of the EPA response in this *Response to Comments* document.
